DIVISION OF THE NERVES AND TENDONS OF THE HAND

WITH A DISCUSSION OF THE SURGICAL TREATMENT AND ITS RESULTS¹

SUMNER L. KOCH M.D. F.A.C.S. AND MICHAEL L. MASON M.D. F.A.C.S. CHICAGO

IT is inevitable that men who are working along similar lines and who are interested in the same subject should often arrive independently at similar conclusions. In expressing such conclusions one may unwittingly assume that he is stating something that has not been expressed before and fail to realize that other workers in the same field have, perhaps long before, stressed the very facts and principles that have come to seem to him of fundamental importance. A few years ago in discussing the immediate treatment of injuries of the hand we emphasized the importance of a careful examination to determine the nature and extent of the injury before any operative treatment was attempted. Doubtless the same idea has been voiced by many men, but we only realized a few months ago that Torr W. Harmer (28) in 1922 had stressed it so definitely and described the method of examination so clearly that we seemed almost to be taking the words from his mouth.

Similar statements could doubtless be made concerning many of the details of technique which are suggested in the following pages. Incisions which avoid flexion creases and which permit one to lay an intact flap of skin and subcutaneous tissue over sutured tendons and nerves have been advocated particularly by Bunnell² and by Harmer.

¹"It is important to have the skin incision remote from the tendon graft and tendon suture." Bunnell (20).

²From the Department of Surgery, Northwestern University Medical School. Read in part before the Boston Orthopaedic Club, Boston, Massachusetts, April 22, 1932.

The importance of avoiding trauma and of handling tissues with the utmost gentleness is a primary article of faith with good surgeons everywhere. It was one of the principles that Halsted implanted so deeply in the minds of all his students.³

In connection with the surgical treatment of nerve and tendon injuries the importance of such technique has been frequently emphasized by both Bunnell and Harmer by Steindler by Stooler by Naffziger by Garlock by Pollock and Davis and by many others. Bunnell in 1921 presented a paper entitled "An Essential in Reconstructive Surgery—Atraumatic Technique," devoted essentially to this one point, and in his later papers

³"All of his publications had a very practical application, many of them precedently so. For example, his introduction of the use of rubber gloves in surgery; his insistence upon the most meticulous care in the gentle handling of tissues, alginate asepsis and complete hemostasis." Farney.

"He learned how to treat the tissues as he made the wound that was later to heal. He treated them tenderly and watchfully, gently separating them and trying with extremely fine black silk every minute bleed his vessels—so that in the course of his dissection everything was left clean and dry and above all not bruised or strained. Usually careful was his attention to the bringing together of the tissues when the wound was to be closed—fascia exactly suited to fascia, muscle to muscle, layer to layer, and finally the skin with carefully placed sutures." McCallister.

He demonstrated that a operation lasting three and even four hours, if all the principles of surgery were utilized, did little harm to the patient. His painstaking devotion to hemostasis, to sepsis, to the delicate handling of tissues and to the artistic finish of his handiwork were of the greatest value to surgery. He introduced new hemostatic forceps with small jaws at the crutching points so that a minimum of tissue beyond the vessel was injured; he demonstrated the great decrease in the reaction in the wound when fine silk ligatures were used that included only the injured vessel and his representation of a wound attempted to bring together the tissue layer by layer as they belonged and without leaving dead spaces. His cases were a forcible demonstration of the fact that if the volume of blood is not diminished and the patient not otherwise traumatized, the duration of the anesthetic is of relatively little importance. Cather.

constantly emphasized its importance. How well his results have justified his teaching is attested by Mayer's tribute. His work is famous the world over. There is no one who can do what he can. His results are accomplished by a technique that rivals that of the most proficient musician. His paper on

Reconstructive Surgery of the Hand is the best article we have read on the subject. It could well serve as a textbook for every surgeon who is seriously trying to achieve good results in hand surgery.

The contributions of Leo Mayer and Steindler to the subject of tendon surgery are equally well known to every worker in this field. Mayer's original papers on the anatomy and physiology of tendons and his monograph on tendon transplantation written in collaboration with Professor Biesalski are outstanding contributions to the surgery of tendons.

In addition to the men mentioned are many others,—Auchincloss, Garlock, Mather, Bloch and Bonnet, Iselin—whose names need only be mentioned to recall to the reader their interest in the surgery of tendons and the many helpful suggestions they have made toward its improvement.

We are equally indebted to another group of workers who have concerned themselves particularly with the physiological and pathological changes involved in nerve injuries, with methods of repairing such injuries, and with the clinical symptoms and signs following injury and operative treatment. The experimental studies of Howell and Huber, of Kirk and Lewis, and of Ranson on the processes of nerve degeneration and regeneration, the experimental work of Huber and his colleagues on nerve suture and nerve transplan-

tation and the careful clinical studies of Pollock on a large number of patients who had sustained various types of nerve injury are outstanding contributions in the American literature. Naffziger's paper on end-to-end suture of peripheral nerves is an admirable and comprehensive presentation of the technique of nerve suture. It is one of those contributions to which the student continually returns for helpful guidance. Stookey's well known volume on the surgical and mechanical treatment of peripheral nerves, Lewis' chapter on peripheral nerves in *Lewis' Practice of Surgery*, Foerster's encyclopedic monograph on the anatomy and physiology of the peripheral nerves, and on gunshot wounds of the peripheral nerves, and Pollock and Davis' monograph on peripheral nerve injuries are more recent contributions which cover in a thorough and exhaustive fashion the entire subject of peripheral nerve injury and repair. Babcock and Bower, Bunnell, Delagénère, Eisberg and Sonnenschein, Elsberg, Frazier, Joyce, Kennedy, Platt, Scutlar and Twining and Stopford are only a few of many others who have made helpful contributions to the subject of peripheral nerve surgery.

Finally we personally are very greatly indebted to Allen B. Kanavel for the helpful advice, the imagination, the enthusiasm and the constant encouragement which he has given so generously to those who have had the good fortune to be associated with him. Many of the cases which are reported in the following pages have been his cases. The technique which we have described is patterned after his teaching, and if we have secured good results it is because we have tried faithfully to carry out the surgical principles which he has striven so hard to instill into us.

A primary consideration in the immediate treatment of an injury with tendon and nerve involvement, and one which is often neglected is a careful examination of the patient to determine the degree and extent of injury.⁴ Its importance may be illustrated by brief mention of a specific case. A man was seen two weeks after he had sustained a transverse cut

over the volar surface of the right wrist. He had been operated upon less than two hours after the injury. His first words were, "I have had no feeling in the palm since the injury." In answer to our questions the surgeon wrote "I know there was no nerve injury for immediately after completion of the operation the patient was able to flex all his fingers."

Aside from the obvious fact that it is impossible to divide the flexor tendons by a

The necessity for careful examination before operation on the injured hand was mentioned above, but we believe the point is of such importance as to justify calling attention to it again.

transverse cut across the volar surface of the forearm just above the wrist without dividing the median nerve and that it is difficult to divide the tendons without dividing the ulnar nerve (Fig. 1) is the often forgotten fact that even if both median and ulnar nerves are divided at the wrist a patient can flex his fingers if the flexor tendons are intact since the long flexor muscles receive their innervation from the median and ulnar nerves high up in the forearm.¹

Textbooks have made the picture of median and ulnar nerve injury unnecessarily difficult to visualize and remember and these particular injuries are stressed because they are so common and so important. There are two pathognomonic signs of median nerve injury below the middle of the forearm—loss of sensation in the area of median nerve distribution (Fig. 2) and the inability to rotate the thumb to face the fingers.² Similarly there are two diagnostic signs of ulnar nerve injury below the middle of the forearm—loss of sensation in the area of ulnar nerve distribution (Figs. 2, 3) and loss of the ability to abduct the completely extended fingers from and adduct them to the midline of the hand. Such movements do not of course represent the entire motor function of the median and ulnar nerves but they are unequivocal and diagnostic.

The function of the radial nerve (Fig. 3), of the digital nerves, of the long flexor tendons of thumb and fingers and of the extensors of the thumb and fingers are too well known to require comment and yet the failure to examine the hand and determine the extent of loss of function of nerves and tendons before carrying out any operative procedure often leads to unfortunate complications. "Forewarned is forearmed," and the surgeon who knows before operation that a certain nerve or

FIG. 1. Dissection of the volar surface of the wrist showing the superficial position of the median and ulnar nerves, and the similarity in size between the median nerve and the superficial flexor tendons (after Sobotta).

tendon has been divided will not fail to find the injured structure and reunite it. How easy it would be to overlook certain nerve and tendon injuries if the pre-operative findings had not made one certain of their presence, the experienced surgeon knows full well.³

¹ So able a surgeon as John B. Murphy in discussing the loss of ability to flex the fingers in a patient who had sustained a deep glow cut across the volar surface of the wrist stated: "there may be something wrong with the median nerve which supplies these muscles and, a little later, if the tendons were cut and then sutured, why is their function now suspended? It must be that the tendons either were cut and not sutured at all, or that they have become immobilized by adhesion to the structures in the neighborhood. A third possibility is that there is some thing wrong with the nerve supply. It is quite possible that the median nerve was divided and not recognized."

Pollock (58) has shown that in cases of median nerve palsy the tip of the thumb can be approximated to the fifth finger by contraction of the flexor pollicis brevis and adductor pollicis. This movement, however, is a pure rotation of the thumb, for the thumb is moved in a plane parallel to the palm.

² The emphasis that has been placed on the pre-operative examination of the injured hand is made with particular reference to the patient who is seen immediately after injury. It is unnecessary to add that the patient who comes for secondary operation should have as careful a examination and as accurate a pre-operative diagnosis as possible. It is why, however, to emphasize the importance of not delaying operation in late cases in which the exact diagnosis is in doubt until the most opportune time for operation, and particularly for nerve suture, has passed. It has favorably been our experience that in cases in which because of evidence of returning sensation there was doubt as to whether the nerve was completely divided, as to whether it had been properly united at the original operation, or as to whether spontaneous recovery was taking place the extent of nerve injury found at operation was considerably greater than anticipated. Frequently in such doubtful cases we have found nerve ends so widely separated that there was no possibility of union taking place without surgical intervention. The careful clinical studies of Pollock, particularly with reference to the development of overlap from adjacent nerves in an area whose normal sensory innervation has been disturbed, have been of very great assistance in helping us to understand these apparent anomalies, and to realize the importance of not placing too great reliance upon the evidence of returning sensation in an area whose nerve supply has once been cut off.

Fig. 3. The sensory nerve supply of the palm (after Spalteholz)

A second and important consideration is that, to the patient who has sustained an injury with division of tendons and nerves, the greatest immediate danger lies not in the fact that function of the tendons and nerves has been lost, but that he has sustained an open wound through which virulent bacteria may gain access to the deeper tissues and in the manipulation and dissection incident to repair of the injured structures these virulent bacteria may be disseminated widely and with disastrous results.⁸ Such infection may jeopardize the patient's life. It cannot help but jeopardize the success of the operation for no single factor is so important to success in the repair of tendon and nerve injuries as healing by primary union.

Although infection does not develop in every case in which immediate suture is performed (Figs. 4, 27, 28) it happens far too often. During the past year we have seen six patients, two of them physicians, in whom the immediate suture of divided tendons was followed by spreading infection, extensive sloughing, long continued suppuration and eventually healing with marked loss of func-

Fig. 4. The sensory nerve supply of the dorsum of the hand (after Spalteholz)

tion. Such complications can be avoided by limiting very definitely the indications for immediate operation and by permitting cases in which these indications are not present to go on to complete healing before attempting surgical repair.

Under what conditions is one justified in carrying out immediate operation? In other words, under what conditions has one a right to expect wound healing without infection? A number of factors come into consideration: the conditions under which the injury has been sustained, the character and extent of the external wound, the exact location of the injury, the first aid treatment rendered, the time that has elapsed since the injury and finally the facilities available for its repair. If a tendon or nerve injury is the result of a clean cutting wound—from a glass, or broken bottle or a porcelain water faucet, sustained indoors, and if the patient's hands are clean, there is a reasonable chance that the wound is not infected (Fig. 4). This possibility becomes less when the patient's hands are soiled or covered with dirt and grease when the injury is sustained out of doors—from flying glass, broken windshields, etc. and when the external wound is a jagged lacerated wound of considerable extent (Fig. 5). The exact location of the injury is of importance. Tendons

⁸ Gieseler has emphasized the importance of delaying operation on injured tendons "when the wound is jagged and dirty, obviously grossly contaminated and the surrounding skin is covered with grease and dried blood." We agree entirely with Gieseler's statement, but would limit much more strictly and definitely the indications for immediate operation.

Fig. 4a.

Fig. 4. Division of median nerve, of flexor carpi radialis, abductor pollicis longus, palmaris longus, and partial division of flexor pollicis longus and flexor sublimis of index finger from a fall on a broken water bottle. which are surrounded by definite sheaths are more vulnerable than those which are surrounded only by areolar tissue. Infection introduced into an open tendon sheath spreads readily from one end of the sheath to the other and very quickly involves its entire extent. If no sheath is present localization of the infection is favored and widespread diffusion of an infectious process is less likely to take place. The first aid treatment is of importance. If considerable bleeding occurs bystanders become alarmed and often contaminate the wound in their anxiety to control the hemorrhage. The time element is important. If the injured hand is seen immediately, there is little opportunity for bacterial growth to take place, but if more than four hours have elapsed we believe it is unwise to attempt primary operative repair. Finally it seems unnecessary to say that the suture of divided tendons and nerves is a major operation and one that should not be performed except in a well equipped operating room yet one fre-

quently sees cases in which such repair has been attempted in a doctor's office or a hospital emergency room with results that are far from ideal and difficult to counteract.

To state it in positive terms instead of negative terms it is our belief that an immediate repair of divided tendons and nerves is justifiable if the wound is a clean cutting wound made by sharp instruments if the wounded hand is clean if the cut is sustained indoors if the first aid dressing has been sterile if the patient is seen within a few hours of the time of injury and if a well equipped operating room is available for surgical treatment.

If the median or ulnar nerve alone has been divided, without injury of tendons, one is justified in performing an immediate suture in some cases in which with extensive tendon injury immediate operation would not be justified because divided nerves do not retract as divided tendons do and an extensive dissection to expose them is rarely necessary, and because the results of immediate nerve suture

Fig. 5a.

Fig. 5b.

Fig. 5. Division of extensor tendons of index, middle and ring fingers by the edge of a broken mirror. particularly as regards the return of motor function are so much better than the results of delayed suture that one is justified in taking a somewhat greater chance in order to secure an immediate end-to-end apposition.

If the conditions described above are not present it is wiser to close the superficial wound loosely with a few interrupted sutures and permit healing to occur before attempting repair of the injured tendons and nerves (Figs. 6-7). One should be particularly conservative about attempting immediate suture of tendons surrounded by a sheath. One occasionally sees cases in which the suture of tendons on the back of the hand has been followed by a slight localized infection without serious impairment of the operative result (Fig. 5) but we can recall but one case in which a low grade infection developed after suture of flexor tendons without impairment of the final result. In the majority of such cases which have come under our observation there has been extensive spreading of infection with eventual necrosis and sloughing of tendons, and in some cases sloughing of superficial tissues and ankylosis of joints as well—conditions which make it necessary to postpone any attempt at operative repair for long periods of time and often make operative restoration almost impossible to accomplish.*

*Our emphasis upon the importance of delaying nerve and tendon su-

It is not necessary to present examples of the poor results of primary tendon and nerve suture. They are sufficiently common to have inspired considerable distrust in the medical profession concerning the wisdom of any operation upon tendons and nerves. On the other hand, it is hardly necessary to emphasize the fact that excellent results can be obtained in cases in which operation has been delayed until the original wound is soundly healed and free from every evidence of infection.¹⁹ The duration of this delay depends upon the time required for wound healing, the character and amount of wound secretion and the bacteriological findings. Wounds which heal by primary union can be safely reopened three weeks after the injury. If any wound discharge has been present it is wise to wait for three months after the wound is healed before carrying out secondary repair (Fig. 8). If the infection has been due to a hemolytic streptococcus we believe that one must wait until the wound has been completely healed and free from discharge for twelve months

try unless one is certain that the wound is not infected is the result of our own early experience with few cases in which we performed primary nerve and tendon suture and our observation of the results in considerably larger number of cases in which immediate operation had been carried out elsewhere.

Our own results following immediate nerve and tendon suture are discussed in more detail under "Removal of Cases of Divided Nerve and Tendon." (pp. 31-34.)

No operator in the face of infection is to court disaster. Eyle, Although the writer was referring to the treatment of peripheral nerve injuries resulting from gunshot wounds the principle holds true no matter what the cause of the wound.

before he can carry out extensive secondary operations without danger of lighting up a latent infection

OPERATIVE TECHNIQUE

In the surgical treatment of tendon and nerve injuries several technical details are of great importance. First of these is care to ensure asepsis. In our judgment nothing in the way of surgical skill, accurate apposition of tendons and nerves, postoperative care, or postoperative physical therapy can compensate for failure to secure healing by primary union.¹¹ To render such healing as nearly cer-

tain as possible the hand and forearm are carefully prepared by thorough and prolonged cleansing with soap and water the afternoon before operation. A sterile dressing is then applied and left in place until the patient reaches the operating room. Just before operation the hand and forearm are painted with a solution of five per cent picric acid in fifty per cent alcohol.¹² An area on the ab-

very exceptional occurrence. Therefore the greatest care to prevent the entrance of organisms into the wound is a rule the importance of which cannot be overestimated. Kennedy

"11. the occasional case in which we have had the opportunity of operating upon patients with divided nerves and tendons within a few hours of the time of injury. It has for some years been our custom to prepare the field of operation in the operating room and, if general anesthetic is given, after the patient is anesthetized.

Sterile dressings are laid over the wound itself and a wide area around it shaved and cleaned with soap and water. Next the wound itself is carefully cleaned with soap and water and with the help of small gauze

¹¹ Aseptic technique of a high standard is essential if good results are to be expected. It is no proof to the contrary if a case of nerve suture has become septic and yet a good result has followed. It will certainly be

dominal wall from which subcutaneous fat can be obtained is prepared in the same way and if there is a likelihood that tendon grafts will be needed a foot is also prepared. In the operating room sterile linen is applied in such a way that hand, abdomen and foot are accessible without shifting the sterile linen once it is in place.

Everyone who enters the operating room is masked the nose is covered as well as the face for we are convinced by our own clinical experience, and by Meleney's bacteriological studies that serious wound infection can result from failure to mask the nose as well as the mouth of everyone in the operating room.

sponges held in sterile forceps. The final step in cleansing is irrigation of the wound with considerable quantity of warm sterile water.

We believe considerable harm is done to delicate and fragile tissue cells by irrigating with a wound with powerful chemical solutions, such as tincture of iodine, 95 per cent alcohol, etc. and that this harm outweighs any possible good that can be accomplished.

Although approximately one third of our cases have been operated upon under local anesthesia we prefer to use nitrous oxide, ethylene or ether unless there is a contra indication for so doing. Scar tissue particularly is difficult to infiltrate and render anesthetic by local infiltration. The injection itself adds a certain degree of traumatism. If tissues, particularly covering tissues are already devitalized we cannot with safety use an anesthetic solution containing adrenalin and solutions without adrenalin do not render the part anesthetic for a long enough time to permit one to carry out a complicated operation. Finally the pressure of the blood pressure band may become unduly painful for the unanesthetized patient after 30 or 40 minutes and make it necessary to release the constriction just at the moment when a bloodless field is essential.

Brachial plexus anesthesia has certain theoretical advantages. Practically we have found it difficult to secure constant and satisfactory anesthesia with this method and in attempting it we have always been concerned with the possibility of doing harm to important nerves or blood vessels by such a blind procedure.

Just before the operative incision is made the extremity is elevated for a few moments and the blood pressure cuff applied beforehand, inflated to 220 or 230 millimeters. A bloodless field is indispensable for careful and accurate dissection and suture.

Finally it should be unnecessary to repeat that gentleness in the handling of tissue as has been so forcefully emphasized by Bunnell,

Fig. 8a.

Fig. 8b

don clamp to facilitate tendon suture we have finally come to depend upon very simple instruments: fine tissue forceps with teeth, so called Adson forceps; very fine straight arterial needles for tendon and nerve suture; No. 10 D Corticell white silk for the retention suture in the tendon and No. 6 Corticell black silk for the coaptation suture in the tendon and for nerve suture; fine round needles with fine silk for suturing the deep fascia and subcutaneous tissue, and fine cutting needles with fine der-

Fig. 8. Division of nerves and tendons of volar surface of forearm just above wrist from fall on a piece of glass; nerve and tendon suture elsewhere 2 hours later; primary union, persistent loss of sensation in palm and inability to extend fingers. At operation 3 months later median nerve and flexor tendons found fused into a single mass containing many strands of coarse silk at the site of the divided ulnar nerve was a pecan sized abscess filled with gelatinous,

purulent fluid. Contents of the abscess carefully wiped out; neurolysis of median nerve; tendolyses of flexor tendons, and end-to-end suture of ulnar nerve. Operative wound redressed and tender for some days, but healed by primary union. Cultures of abscess showed slowly growing colonies of staphylococcus albus. a. Before operation. b. Result 7 months after operation; the fingers can be flexed completely and extended almost to a straight line.

by Harmer by Naffziger by Pollock and Davis and many others. It is of paramount importance in the treatment of nerve and tendon injuries. This gentleness must be directed not only to the handling of nerves and tendons but to the superficial tissues as well. Necrosis of skin edges along the line of suture may result from forceful retraction and rough handling with tissue forceps and Allis forceps. Skin flaps often have diminished vitality because of the original injury and the subsequent scar tissue formation. Care and gentleness throughout the operation are important factors in helping to secure the primary wound healing which is so essential a factor in bringing about a successful result.

Although we have used special instruments for holding tendons and have devised a ten-

mal suture or silk for the closure of the skin.

A sterile bipolar electrode to stimulate an injured nerve with the faradic current and enable one to determine the presence or absence of conducting fibers has been recommended by some surgeons as an essential feature of the operating room equipment. Although we have constantly kept such an apparatus available we have not found it of practical value. In the great majority of cases in which we were in doubt as to whether nerve division had been complete or whether spontaneous recovery was taking place we have found at operation unmistakable evidence of extensive injury, usually greater than we had anticipated. In a number of cases of median nerve injury, for example, in which the return of sensation in the area of median nerve distri-

Fig. 9

Fig. 10. Method of approximating the ends of divided tendons. a. The preferred method. b. An alternative method. c. Method of approximating the fragmented ends of scarred tendons when end-to-end union of freshened tendon ends is impossible because of extensive destruction of tissue.

Fig. 9. Preferred incision for exposing divided nerves and tendons over the volar surface of the wrist

bution suggested that recovery was taking place we have found the nerve ends widely separated and in other cases the proximal segment of the nerve united to a tendon and the distal segment lying free in the scar tissue floor of the wound. In no case in which the pre-operative examination left us in doubt as to whether recovery was taking place and in which at operation nerve ends were found united by a fairly normal appearing spindle of scar tissue were we able to secure a response from electrical stimulation of the nerve in question and therefore determine that resection of the neuroma and suture would not be necessary. In the majority of such doubtful cases resection of the scar tissue showed smooth connective tissue uniting the nerve ends and forming a complete block to the downgrowth of axons. Occasionally the excised section showed on its cut surface a few apparently intact nerve fibers, but in these cases also stimulation of the nerve above the site of injury had failed to produce contraction of the muscles supplied by the nerve in question.

INJURIES OF THE VOLAR SURFACE OF THE FOREARM AND WRIST¹³ (Figures 4, 6 7 8 13 14, 16 17 18 41 42 43)

The incision is planned if possible so that a flap of skin and subcutaneous tissue overlies the line of tendon and nerve suture (Fig. 9).

In the following discussion of the technique of operation in different locations and the operative technique of choice we have included the cases

in which it is very difficult to secure accurate and complete apposition of skin edges at and above the wrist when it is necessary to flex the wrist to permit nerves and tendons to come together without tension but the difficulty is lessened if the incision crosses the flexion fold at the wrist near its radial or ulnar border.

After the incision is made the median nerve is dissected free, first above and then below the site of injury. It is always sought in sound tissue, and traced from above and below to the site of injury.¹⁴ Just above the wrist except for the palmaris longus, it is the most superficial structure underneath the deep fascia (Fig. 1). Higher in the forearm it lies at a deeper level between the superficial and the deep flexor tendons. It can be distinguished by its slightly dull grayish-white color in contrast to the glistening yellowish white of the tendons, by its faint longitudinal striations, and by the tiny blood vessel that often lies upon its surface. It cannot be differentiated from the tendons among which it lies by its size. This probably accounts for the fact that in secondary operations one often finds the proximal segment of the divided median nerve sutured to the distal segment of one of the divided tendons. In locating the distal segment of the divided median nerve one should remember that it lies directly underneath the transverse carpal ligament. The ligament is thick and tough; it often closely resembles scar

in which operation is carried out after wound healing is complete, in other words, the secondary operation. If one has the opportunity of operating upon a case immediately after injury seriously he will accept the operative measures in the open wound which is already present.

A long incision. Identification of the distal and proximal portions of the nerve in their normal relations above and below the scar is the first step. McAllister.

Fig. 11 Harmer's method of approximating the ends of divided tendons. (Reprinted in M. & S. J. 1914, clxxvii, 805-810.)

Fig. 12 Bunnell's method of approximating the ends of divided tendons. (J. Bone & Joint Surg. 1925, 3, 10.)

tissue. Time can be saved by immediately dividing it in a longitudinal direction at the level of the wrist joint. The nerve can then be easily identified as it lies upon the flexor tendons just under the ligament.

After the median nerve is found the ulnar nerve is sought as it lies under cover of the flexor carpi ulnaris just medial to the ulnar artery and vein. In the forearm the accompanying blood vessels help to make easy its identification. The distal segment is more difficult to find particularly if the point of division is close to the wrist. One should remember that as they pass from under cover of the flexor carpi ulnaris the nerve and its accompanying vessels lie just lateral to the pisiform bone, covered by a fascial expansion of the flexor carpi ulnaris (the volar carpal ligament) and that they pass into the hand superficial to the transverse carpal ligament.

In contrast to the median nerve which passes underneath the ligament. Not infrequently one finds the ulnar nerve divided just beyond the site of its division into deep and superficial branches. Both deep and superficial branches must be found and united to the proximal nerve trunk if one is to secure a satisfactory result.

With the nerves freed, covered with gauze or cotton saturated with salt solution and held out of danger the tendons are next identified. Divided tendons always retract and one must lengthen the incision if necessary in order to reach them. When the ends are exposed they can be grasped gently with fine tissue forceps and freed from the surrounding tissues by sharp dissection as far distally as one can see and reach with the knife. The superficial group is separated from the over-

Fig. 13. Partial division of ulnar nerve, complete division of median nerve and all of flexor tendons from fall on a glass bottle. Immediate closure of wound elsewhere. Primary union. Secondary operation 3 weeks after injury, suture en masse of proximal segments of deep flexors of

four fingers to distal segments; suture of superficial flexor tendons in same way; end-to-end suture of flexor pollicis longus, of median nerve and repair of ulnar nerve. Primary union. Result 3 1/2 months after operation. Patient is developing ability to flex fingers individually.

Fig. 14d.

moistened with salt solution¹³ and the retracted tendons drawn proximalward into the wound. In favorable cases the adhesions which have formed in the digital sheaths give way and one can draw the fingers into complete flexion. In other cases the adhesions between the tendons and their sheaths have become so firm that no amount of tension can produce flexion at the interphalangeal joints. If one cannot produce flexion by direct tension upon the tendons one cannot expect the flexor muscles, which have been inactive for some time to produce such flexion after suture has been performed no matter how perfect the healing at the line of suture may be. In such

Fig. 14. Printing press injury just below middle of left forearm with division of median and ulnar nerves and all flexor tendons except flexor pollicis longus. Immediate nerve and tendon suture elsewhere with persistent drainage for 2 months, no functional improvement. Secondary nerve and tendon suture 5½ months after injury primary union. a. Condition before operation. b. Result, year 8 months after operation, although proximal segments of deep tendons were sutured en masse to distal segments, and superficial tendons united in same way patient has individual action of the index and middle fingers, but ring and little fingers are flared and extended as one. c, d. lying fascia and from the deep group and the deep group from the sides and floor of the carpal tunnel. When the surrounding adhesions have been divided not torn as completely as possible the ends of the tendons are grasped between the finger tips covered with gauze

cases in order to secure the desired result we have found it necessary to make an antero-lateral incision in each finger and free the ten-

¹³ Whether we are dealing with tendons or nerves we must handle them as little as possible. I prefer to hold the structure with force of moist gauze in my fingers rather than to subject them to the excessive compression of smooth forceps, the bite of toothed forceps, or the burning of dry heat. Harner (16)

Fig. 15a, c, d, e

Fig. 15a

tion on suture helps to rotate nerve and facilitate introduction of next suture. e Suture completed f Protection of line of suture with thin fat transplant

dons from the surrounding tissues by sharp dissection. When this is done the firmest adhesions are usually found at the point of bifurcation of the sublimis, where the tendon of the profundus passes between the two slips of the dividing sublimis and at the proximal end of the digital sheath opposite the metacarpophalangeal joint. We have not been successful in attempting to free the flexor tendons from adhesions to the digital sheaths by 'coring them out' with a modified cork borer.

If nerve destruction has taken place as a result of fibrosis or infection nerves must be freed for a considerable distance proximal ward so as to permit the ends to be brought together without tension. Some relaxation can be obtained by volar flexion of the wrist but if this does not suffice the proximal segments of the nerves must be freed until complete relaxation is obtained.¹⁴ By carefully

Fig. 15f

separating the muscle bellies of the flexor sublimis from the underlying flexor profundus digitorum the median nerve can be freed almost to the elbow with little traumatism and without destruction of blood vessels. Flexion at the elbow gives still more relaxation. If both median and ulnar nerves are involved, and the loss of tissue is so great that the nerves must be freed to the elbow and the elbow flexed to relax the median nerve it is necessary to isolate the ulnar nerve at and above the elbow, divide the fascial origin of the flexor group of muscles from the medial condyle and displace the ulnar nerve from the olecranon groove to the front of the elbow. As Naffziger has emphasized one should be careful to preserve intact the branches of the nerve to the long flexors of the wrist and fingers. With the ulnar nerve displaced in front of the medial condyle flexion at the elbow relaxes the nerve instead of making it more taut.

trauma and do not secure the greatest lengthening. The attachments of the nerve sheath to surrounding fascia will not be freed by peeling. It is often found that free mobility is prevented by small nerve branches to vessels. Careful exposure of these and gentle dissection of them for some distance up the nerve trunk will be necessary before the desired freedom of movement is obtained." Naffziger

¹⁴ Free mobilization of the nerve requires, above all, long fasciotomies. Small fasciotomies and forcible stretching of the nerve produce unnecessary

operation. b. Operative findings. Solid black lines indicate divided tendons. c. Result 3 years after operation. d. Sensory return almost complete 3 years after operation.

e. Tracing of hand showing degree of abduction of fingers possible 3 years after operation. The most definite evidence of return of motor function of the sutured ulnar nerve.

After the dissection is completed and the nerves and tendons are ready for suture the air is released from the blood pressure cuff and any actively bleeding vessels are ligated. The arm is then elevated for a few moments, the cuff reinflated and the constriction maintained until the operation is completed and the bandage applied over the dressings. We have given up attempting to perform tendon and nerve suture in a bleeding field. The oozing from many tiny blood vessels is so great that the field of operation soon becomes discolored and the structures involved diffi-

cult to recognize. The amount of blood so lost is not inconsiderable and the trauma to tendons and nerves from repeated sponging is surely not helpful.¹⁷

Bassett has said, "A tourniquet or blood pressure band should always be used to avoid the trauma of sponging" (p. 12). If we operate in a field rendered bloodless by the use of blood pressure band or tourniquet, we may avoid the unnecessary trauma of sponging, and can by clearly seeing the tissues direct with accuracy and minimum of traumatism (p. 14). Taylor has said, "It is hardly necessary to mention that this work should be done in a bloodless field to secure close recognition of the parts and to avoid the necessity of sponging, which if repeated, should be done with moist absorbent cotton and not wiped with gauze."

Some surgeons on the other hand have advised against the use of a constriction on the ground that "protracted constriction may not only affect the nerves, but the interference with circulation may so disturb the nutrition of the parts that repair processes may be retarded and resistance to infection reduced. Furthermore, prolonged use of the tourniquet may be followed by postoperative swelling" (Harnier (18)).

Tendons are sutured first and if possible are sutured end-to-end. The type of suture we prefer to use is shown in Figure 10a. This type of suture has been advocated by Friedrich and by Max Lange of Munich. It is not essentially different from the technique advocated by Harmer (Fig. 11) and by Bunnell (Fig. 12). It fulfills the essentials which Mason and Shearon in their experimental studies on tendon suture have found to be of primary importance viz. firm and accurate apposition of tendon ends without interposition of knots between the apposed ends and

FIG. 10a

FIG. 10b

Fig. 17. Division of median and ulnar nerves and of all flexor tendons as result of glass cut in automobile accident. Immediate nerve and tendon suture elsewhere—primary

union but with incomplete restoration of function. Secondary nerve and tendon suture 6 months after injury. a Before operation. b Result 12 months after operation.

without suture material threaded through the central portion—the core as it were—of the tendons. Sutures so placed these workers have found act as irritating foreign bodies at the very site where rapid and unimpeded proliferation of tendon and sheath tissue should go on if prompt and firm union is to take place.

If all the tendons are matted together at the site of division and the operation is a tedious and difficult one we do not always separate the individual tendons of the superficial group and of the deep group to the four fin-

gers from one another. In children, particularly, we have sometimes sutured the four superficial tendons above *en masse* to their respective tendons below, as though we were dealing with a single tendon, and have united the four deep tendons in the same way. In such cases we have still secured excellent results as far as individual action of the fingers is concerned (Figs. 13, 14). If healthy clean-cut tendon ends cannot be approximated, and the tendons can only be brought together by utilizing the strands of fibrous tissue which have bridged the gap between the ends of the divided tendons these strands are united by side to side union with fine silk sutures (Fig. 10c). If the latter method cannot be utilized, tendon grafts are taken from the foot to bridge the defect.

After the tendons are sutured the exposed nerve ends are amputated in succession. This

With a blood pressure apparatus and the motor driven belt and with constriction mal tournant the wound has been restored and the pressure bandage applied over the suture. A support is secured by stay of the arm on the rest of the hand. A letter is particularly with regard to the use of the motor driven belt. The swelling and the wound than when we use the motor driven belt. The use of constriction with the motor driven belt is a part of the operation.

Again, we repeat, we are not using the primary part of the hand in the operation. We are using the hand in the operation. We are using the hand in the operation. We are using the hand in the operation.

slices until healthy nerve ends are reached. The nerves are united end-to-end by very fine silk sutures which include only the epineurium (Fig. 15).¹¹

In the light of our present knowledge and as the result of our experience with three cases in which extensive gaps in nerves were bridged with fascial tubes, we have not felt justified in attempting any other methods of repairing divided nerves.

The value of plastic procedures or of nerve transplants to bridge a gap between divided nerve ends is still a controversial question. Two aspects of the subject we believe have not received the attention they deserve. The experimental work of Huber, Lewis, Corbett, Stookey, and Roberg on the use of nerve transplants was carried out on healthy animals; a segment of normal nerve was excised and immediately replaced by some type of graft. In only a few cases on record has a similar procedure been carried out in man. In the great majority of cases in which nerve transplants have been performed in man, a considerable interval of time has elapsed between the injury and operation, with resulting atrophy of all the tissues innervated by the divided nerve and degeneration of its distal segment. Not infrequently there has been severe wound infection and extensive scar tissue formation as well. Under

Many technical details have been emphasized with regard to the exact method of nerve suture. The essentials are delicacy of handling and the avoidance of trauma; accurate suturing without tension; with the use of a minimizer amount of foreign material to favor the production of fibrous tissue; and the proper protection of the parts afterward. Valdezger.

Catgut and especially the tension catgut sutures of Gossel, so generally used, we have carefully avoided after observing the absorptive reaction and disintegration produced. Nerves by the catgut used abroad, and the absence of reaction from fine silk. Hatcher and Flower.

Fig. 19. Aluminum splint for maintaining volar flexion at the wrist after suture of the ulnar nerve.

such conditions the problem is obviously a different one from the transplantation of a healthy living nerve graft or of a preserved graft into normal tissue to replace a newly made defect in a normal nerve. In the second place, as Pollock has so clearly shown, careful discrimination must be used in interpreting the clinical symptoms present after operations on nerves. One must be particularly careful not to confuse the residual sensibility due to overlap of adjacent nerves with return of sensation due to nerve regeneration and not to confuse supplementary movements and re-education of normally innervated muscles with return of motor function in muscles supplied by the divided nerve.

With reference to the value of nerve transplants or of plastic operations on nerves, Lewis stated (41):

I believe that I have two cases in which there are decided evidences of return of function after the use of the auto-cable transplant. Nine years later he stated (42): "Accurate end-to-end suture gives the best results and should be performed in all cases when possible and a number of different procedures have been employed to bridge a defect in a peripheral nerve so long that an end-to-end suture cannot be made. Fdinger introduced the formalized calves' arteries. Tubes of Cargile membrane, fascial tubes, and decalcified bone tubules have all been used. Occasionally a success has been reported

tary movements should be considered. These procedures cannot be depended upon and should be discarded.

The transplantation of segments of nerves has been attempted from time to time auto- homo- and hetero-grafts being used. Eden, for example, removed the ulnar nerve in the case of an amputation and transplanted it into a defect in the musculospiral measuring 20 centimeters. After two years there was no improvement. Transplantation of segments of nerves has been repeatedly attempted with almost uniformly bad results. Occasionally a success has been reported. In some of the cases which have been operated upon the second time some neurofibrillae have been found in the transplant but they have not progressed far.

"Cable transplants have been tried without much success. Segments of nerves preserved in alcohol, as suggested by Nagotte, are not successful.

Tubulization and grafts experimentally employed have given a great deal of information con-

Delageniere in discussing the surgical repair of peripheral nerves in the light of the results obtained in 3,5 wounded men stated that in 94 cases "fasciculi sutures" were performed. In 8 of these the gap between the nerve ends was bridged with strands of catgut. In 8 the nerve was partially divided and reversed. In 3 the two living ends of the nerve were anastomosed with an adjacent nerve. All of these operations resulted in failure. In 65 cases in which the resection of one or both ends of the nerve was insufficient there were 22 failures. With reference to "distant suture" (bridging a gap with strands of catgut) tubular suture (bridging a gap with a tube of autoplasmic or heteroplasmic substance) and neuroplastic methods he says: "No good results have followed these procedures. With reference to autotransplants he says: 'I have used the autoplasmic graft with some results. I took portions of the musculocutaneous nerve of the leg. I have had a complete recovery with the radial nerve and two very fair results with the ulnar. How can we explain these results in the case of the ulnar which is a mixed nerve? Whatever the explanation may be it has been proved true that by means of grafting fragments of the musculocutaneous nerve of the leg as long as 13 centimeters the peripheral nerve has recovered its function.'"

Bunnell reported very striking results following nerve transplantation—6 successful results in 6 cases.

Stokey has summed up the situation admirably.

When all procedures to obtain end-to-end approximation have failed, and a nerve defect remains to be bridged, there is only one method which has shown promise, histologically and experimentally, namely cable transplants of autogenous

nerve segments. The experimental evidence presented by such painstaking investigators as Huber (1895-1918) (Cajal (1918) and others has been so overwhelmingly in support of this method that it cannot readily be discarded. Clinically, however, the percentage of failures is very great. This pronounced difference between the clinical and the experimental evidence must be considered.

Clinically transplantation has been used as a last resort when all other procedures have been abandoned. Under such circumstances the defects

Fig. 24c.

drawn from experimental work. In view of this and of the sound principles involved, it would seem expedient not to condemn this method as yet."

Care is used not to rotate either segment of the nerve in approximating the divided ends.

Stoffel and his followers emphasized the importance of such care in order that corresponding funiculi of the divided nerve segments might be brought into exact apposition and that sensory and motor fibers above might be brought into contact with sensory and motor fibers below. The anatomical studies of Heinemann, Borchardt and Wajsmanski, Langley and Hashimoto, and others, however showed that "a definite funicular arrangement is found only within a short distance of the point at which nerve branches are to be given off" (Stokey) and that because of the many internal plexuses present in the peripheral nerves "the motor paths lie more or less constant only a short distance from the

to be bridged are unusually long and in many instances the nerve grafts are placed in a dense scar bed. Often interstitial sclerosis in both the central and distal segments of the nerve is present. Under such circumstances successful regeneration by any method, even end-to-end suture an infinitely simpler method, requiring less skill and fastidiousness, would be seriously jeopardized.

"Many failures are to be attributed to faulty technique rather than to the method itself.

"In view of the above facts, there is little wonder that nerve grafts are generally considered of no clinical value. Scattered through the literature, however, are quite a few reports of successful regeneration following the use of transplants, among them those by Gosset Delagènière, André-Thomas, and Villandre, Forrester Brown Joyce, Frauder and Stooker. These reports show that clinically nerve defects can be bridged by nerve transplants, thus supporting the foundations laid and the conclusions

point at which they leave the nerve stem (Borchardt and Wjaszowski). Huber as a result of experimental studies stated: "I am confident that it is not necessary in practical work to give undue stress to Stoffel's studies on the specific funicular structure of nerves. Any one who has worked experimentally with regeneration of nerves realizes that from 10 to 50 new neuraxes may bud toward the periphery from a single central neuraxis, and 15 or 20 new neuraxes are often found centrally in a single old neurilemma sheath. No matter how carefully primary suture is made, there is a great tangle of these new nerve fibers as they pass through the connective tissue of the wound, and especially is that the case with secondary sutures. A large number of fibers pass from the stump along the transplant in the connective tissue surrounding the transplant. I am sure sensory nerve fiber branches reach the motor nerves and that central motor nerves reach the distal sensory nerves and are maintained for a time. They make no distal connection and in time degenerate."²

The nerve suture can sometimes be facilitated by inserting a temporary suture through the nerve sheath on the under surface of each segment about an inch from the point of division. Traction on the two sutures helps to draw the nerve ends together and relieve tension while the permanent sutures are inserted.

If the first suture is placed at the very center of the posterior or deep surface of the nerve and a second and third suture inserted at either side of the first suture before the first suture is tied accurate apposition is facilitated. If there is some tension on the nerve ends it is difficult to secure accurate apposition over the deep or posterior surface if the suture is begun on the anterior or superficial surface.

If fat from the subcutaneous tissues at the site of operation can be obtained to separate the deep from the superficial tendons and to protect the lines of nerve suture this is utilized. If not, fat is taken from the abdominal wall and very thin layers of fat laid between deep tendons and carpal tunnel, between deep and superficial tendons and about lines of nerve suture.²³

Conflicting ideas have been expressed concerning the use of a transparent sheet of cellophane and nerves. The recommendations of the older Kohn in this respect are well known. Huber reported an experiment in which subcutaneous fat was wrapped around a nerve transplant in 48 days. The fat sheath was entirely replaced by dense connective tissue. This agrees strongly against fat sheaths in peripheral nerve repair. This conclusion, however, was made on the basis of single experiment.

Later Huber stated, "There is one more point I should like to refer to in connection with my experimental work, namely the importance of having dry clean wounds, before the wound is closed. There would appear to be a correlation between a field not quite dry and an increase of connective tissue about the nerve operated upon. It is now believed that the latter point is the simplest one so far as the formation of case."²⁴

Levitt has said, "After the suture is completed the nerve should be placed when possible in a new muscle bed. The direction should be

Finally the deep fascia and subcutaneous tissue are approximated as accurately as possible with fine silk sutures the skin edges carefully approximated and a massive gauze dressing bandaged snugly in place. Only when the bandage is in place is the air released from the constricting cuff. Since using this method of maintaining a bloodless field we have never found it necessary to open a wound to let out accumulations of blood and have invariably found our wounds soft and free from tension when the primary dressing was changed.

Usually it is necessary to apply a splint to maintain flexion at the wrist for a time and so eliminate tension on sutured tendons and nerves (Fig. 19).²⁰ If flexion at the elbow is necessary to give relaxation of the sutured nerves the splint is designed so as to include the elbow as well.

Active and passive movements of the fingers which do not cause tension upon the line of skin suture are begun at the first change of dressings twenty-four hours after operation. As soon as the superficial wound is healed sufficiently so that more extensive movements can be carried out without danger of separating wound edges active movement and physical therapy are begun and continued daily. The length of time during which flexion at the wrist is maintained depends upon the degree of flexion that has been necessary to permit approximation of tendons and particularly of nerves, without undue tension. The flexion splint is gradually straightened during the second and third week and removed in all cases by the end of the third week.

Fig. 20. Preferred incision for exposing divided extensor tendons over the dorsal surface of the wrist.

INJURIES OF THE PALM (Figures 20 21 22 24 26 40)

The line of incision depends to a certain extent upon the position and extent of the original injury. Four general principles should be kept in mind. An adequate incision reduces operative trauma the attempt to free important structures from surrounding adhesions by subcutaneous dissection is frequently unsuccessful and often leads to futile and unnecessary prolongation of the operation. Second, the incision should follow if possible the normal flexion creases of the palm.²¹ Third the incision can often with advantage be planned so that the old scar is excised. Finally the blood supply of skin flaps must be given due consideration, and any modification of that blood supply which may have resulted from the original injury. As with injuries at the wrist it is very desirable to have a flap of skin and subcutaneous tissue to lay over the line of nerve and tendon suture so that normal tissue may cover the site of repair of nerves and tendons.

After the skin incision is made and the site of injury exposed one must first isolate the

made when possible along intermuscular septa so that the muscle fibers of these muscles which may later be needed to form the new bed for the nerve are not cut. It is not necessary to use any of the numerous methods to cover the suture line which have been advocated.

We believe however that there is logical basis for the use of a precontracted or free transplant of about a sutured tendon or nerve for loose areolar tissue and fat are normally present about these structures, with the exception of those portions of the tendons which are surrounded by definite synovial sheaths. At the wrist or in the hand it is impossible to place the sutured nerves or tendons in a new muscle bed. There is no muscle available. Moreover it has not often been possible in our experience with nerve suture above the wrist to place the sutured nerve in a bed of muscle without dividing muscle fibers obliquely, and bringing about some bleeding at the site of division. All of our experience confirms Huber's statement, quoted above, that there is a definite relation between the dryness of the operative field at the close of operation and the amount of subsequent scar tissue formation.

²⁰ Physiologists have shown that the union of a sutured nerve occurs soon, but is not firm until after four weeks. After this period a sutured nerve cannot be torn off by the normal motions of limbs, even if it was sutured in flexion and there is no danger in putting the limb through gradual progressive movements of extension. DeGaulle

²¹ Many fingers are permanently crippled by the median longitudinal incision. If the median longitudinal incision of the finger, whether on the dorsal or the palmar surface through the matrix or in the pulp whether for infection or repair, be eliminated entirely from the surgeon's activities, many fingers will be saved from being permanently damaged. Even in the palm the longitudinal incision leads to contraction. It is far better to make transverse incisions in the palm in the line of the creases or L-shaped ones than longitudinal. Bannett (1)

digital nerves. These small nerves control the motor function of the lumbrical and thenar muscles, sensation in the palm and fingers, and trophic function of the innervated muscles and in the area of sensory distribution. They lie just underneath the palmar aponeurosis and slightly superficial to the tendons. They are usually bound tightly in the fibrous tissue which holds aponeuroses, nerves, blood vessels, tendons, and sometimes overlying skin in a mass of scar tissue. Unless they are sought and recognized at the very beginning of the operation they may be hopelessly damaged or even remain unrecognized. In these operations there is no royal road. As with injuries at the wrist one must find the nerves above and below the site of injury and trace them from normal tissue into scar tissue. Of particular importance is it to recognize and guard from injury the motor branch of the

median nerve to the thenar muscles, to free it from scar tissue and suture it if divided. The paralysis of the thenar muscles which results from its division and the resulting loss of ability to rotate the thumb so that it faces the fingers are important elements in the loss of function resulting from median nerve injury. The nerve usually appears as depicted in Figure 23 and leaves the sensory digital branch to the ulnar side of the thumb at a level close to the middle of the first meta carpal bone.

Of equal importance is it that the digital blood vessels which accompany the digital nerves should be guarded from injury. Failure to do so may result in necrosis and gangrene of one or more fingers. We have not hesitated to divide the *superficial palmar arch* if necessary to secure adequate exposure or facilitate removal of scar tissue, but whenever possible it has been left intact.

After nerves and blood vessels are freed and protected from injury the tendons must be found. Frequently the divided ends will have retracted a considerable distance from the site of injury and may be difficult to find. Because it lies in a separate sheath and so does not become adherent to the adjacent tendons, the proximal segment of the divided *flexor pollicis longus*, particularly is likely to retract into the forearm and it may be necessary to follow it to a level above the wrist, or to make a separate incision above the wrist in order to locate it (Fig. 24). Often in searching for the proximal segment of a divided *flexor* tendon it is possible to distinguish the thin fibrous tissue remains of the empty sheath or of the areolar tissue which surrounded the tendon in the

FIG. 31a

palm. By putting tension upon this tissue the end of the tendon can be drawn downward in to the wound. The tendon itself is recognized through its covering of areolar tissue by the yellowish tinge at the edge of the cut tendon which is now more or less completely fused with the surrounding connective tissue. This fusion definitely limits its movement but if the adherent areolar tissue is completely excised by sharp dissection free movement of the tendon is again made possible.

In locating and freeing the distal segments of the divided tendons care must be taken to preserve if possible the fibrous tendon sheath or enough of it to act as an annular ligament opposite each phalanx. If this is impossible new annular ligaments must be constructed after the tendon repair is completed.

The problem of uniting tendons which have become widely separated is sometimes a difficult one. If both superficial and deep tendons cannot be approximated without undue tension, the distal stump of the superficial tendon can be excised and a part of the proximal segment utilized as a free graft to bridge the gap between the retracted ends of the deep tendon. In such cases one of the slips of insertion of the sublimis may be left attached at its insertion, laid transversely across the profundus and the free end sutured on the opposite side to the fibrous tissue remains of the flexor sheath, so as to form a new annular ligament to hold the deep tendon in place (Fig. 25).²²

²² One of the great difficulties (in tendon transplantation) is to provide

A thin segment of tendon may also be laid across the deep tendon at the middle of the proximal phalanx and sutured on each side to the remains of the fibrous sheath so as to form a new annular ligament at the level of the web (Fig. 25c) or as Bunnell has suggested a strip of tendon or fascia may be passed around the proximal phalanx underneath the extensor tendon so as to encircle the bone and the flexor tendon. With the ends sutured rather snugly a firm annular ligament is formed to hold the tendon in place over the volar surface of the bone.

If it is possible to bring proximal and distal segments of both superficial and deep tendons to a finger together in the palm without undue tension, the question arises as to the wisdom of having two lines of suture at the same level and in close approximation and whether the two sutured tendons will not adhere to one another and so fail to move freely. We have sometimes met this problem by laying the lumbrical muscle between the two tendons at the line of suture and holding it in place by one or two fine sutures. Figure 26 shows the result obtained in such a case in which both flexors of the index finger and the digital nerves to adjacent sides of the thumb and index had been divided just below the level of the outstretched thumb.

After the tendon repair is completed the

phalangeal annular ligaments where they have been destroyed so as to prevent tendon prolapse. If the flexor sublimis tendon has its dividing slips along the side available, it is possible to use these. If not, it may be necessary to transplant fascia. (Auchincloss (3))

divided nerves must be sutured. In the hand this is often more difficult than at the wrist, for not uncommonly it is necessary to suture two or three small branches below to the larger nerve trunk above. Bunnell has suggested that in such a case the small distal segments may with advantage be gathered into a single bundle by a circular suture before end-to-end suture is performed. The necessity of removing sufficient scar tissue to expose healthy nerve fibrils results in a gap of varying extent between proximal and distal segments. This gap can usually be bridged by freeing the proximal segment above and gently drawing it downward and by flexing the fingers at the metacarpophalangeal joints. Freedom from tension on the line of nerve suture and particularly upon the small and delicate distal segments (the digital nerves) is essential for success.

The use of a thin flap of fat to separate sutured tendons and nerves from overlying skin and to protect the line of nerve suture is helpful in securing a successful result. If subcutaneous fat can be secured at the site of operation it is always utilized, otherwise fat is secured from the abdominal wall.

INJURIES OF THE VOLAR SURFACE OF THE FINGERS

Although tendon division may occur at any point along the volar surface of the proximal and middle phalanges the most common site

of injury of the tendons within the fingers is at their base, approximately at the level of the web. At this level there are three tendons within the flexor sheath—the two halves of the flexor sublimis, separating from one another and passing toward their insertion on the base of the middle phalanx, and the single tendon of the flexor profundus passing underneath the dividing sublimis toward its insertion on the base of the distal phalanx.

In operating upon such cases in earlier years we made the mistake of attempting to suture all the divided structures, and to bring about a complete anatomical restoration. This was always difficult, because the distal slips of the flexor sublimis were invariably short and because they were thin and flat, or slightly crescentic in cross section. Furthermore the suture of three distinct structures at the same level tended to bring together a considerable mass of sutured tissue in a comparatively small space, with the result that the formation of adhesions between deep and superficial tendons was favored and the gliding movement of the tendons impeded.

Bunnell's successful results following the transplantation of a single tendon into a finger from which both flexor tendons had been removed showed that a single tendon attached to the distal phalanx is adequate for maintaining the function of flexion. In cases in which the flexor tendons were divided between the level of the metacarpophalangeal joint

Fig. 33a

Fig. 33b

Fig. 33. Subcutaneous rupture of extensor tendon of middle finger. a. Findings at operation. b. Result 1 year after operation.

and the base of the middle phalanx we therefore began to depend upon the suture of the profundus alone and to utilize the slips of insertion of the flexor sublimis in the construction of a new annular ligament to hold the profundus in place opposite the middle phalanx. This plan of procedure gave more satisfactory results than the former method but the results of suture of the tendons within the fingers are still far from perfect and are less satisfactory than those of tendon suture in any other location.²²

As with injuries in the palm the operative incision is made in such a way as to avoid cutting across the normal folds and creases of the skin, usually along the most accessible lateral surface. The digital nerves and vessels are sought first of all and are carefully protected from injury during the course of operation. The tendon sheath is opened widely enough to expose the tendon ends and free them completely from the adhesions which fix them and to permit careful and accurate suture. Occasionally it is possible to preserve enough of the sheath opposite the proximal and opposite the middle phalanx to act as an annular ligament and hold the sutured tendon in apposition to the phalanges during flexion. Usually, in our

experience this is not possible. Too often as a result of the infection and fibrous tissue formation which followed the primary injury, even though the infection has been minimal, the tendon and the sheath in which it glides freely under normal conditions are converted for some little distance from the site of injury into a solid cord of fibrous tissue. The portion of the sheath left empty by retraction of the ends of the divided tendon collapses. Although at times it may be possible to open the sheath and free the tendon within it, rarely is there sufficient space within the sheath for the sutured tendon to glide freely. Under normal conditions the tendon is held snugly by its sheath. If the tendon is thickened as a result of injury and the insertion of even fine suture material, there is simply not sufficient room for the tendon to move freely.²³ Moreover as a result of the injury the lining walls of the sheath are no longer smooth shining surfaces but are dull and fibrosed. Such conditions favor reformation of adhesions and militate against free movement. We have usually therefore found it necessary to excise the remains of the tendon sheath at the site of injury so as to provide adequate space for the thickened tendon and to depend upon early

²² There are two reasons for this fact: the rapidity with which adhesions form in the finger about the sutured tendon and the relatively poor blood supply of tendons surrounded by synovial sheaths. McWren and Sheehan have shown in their experimental work on tendon suture that the blood supply of the tendon is an important factor in healing, and that sutured tendons surrounded by loose and vascular areolar tissue heal more rapidly and firmly than tendons enclosed in a synovial sheath, and which depend for their blood supply chiefly upon small blood vessels such as are present in the vascular tendons of the flexor tendons in the fingers.

²³ A striking illustration of this fact is the condition known as a snapping finger. Following a comparatively slight injury, such as a sudden pull applied to a finger or sudden hyperextension of an extended finger, the patient complains of localized pain and subsequently develops "snapping," i.e., an interference with complete flexion or complete extension which occurs at a definite and constant point in the arc of movement. At operation there is often found a spindle-shaped enlargement of the tendon just distal to the proximal termination of the flexor sheath in the palm, and this enlargement, though slight, is sufficient to interfere with the free gliding movement of the tendon in its sheath.

movement to prevent the formation of adhesions and fixation of the tendon to the surrounding soft tissues.

The utilization of the slips of insertion of the sublimis tendon as a substitute for the fibrous flexor sheath opposite the middle phalanx has been mentioned. A simple plan consists in the utilization of a single slip which is left attached at its normal insertion and laid transversely across the profundus; its free end is sutured with fine black silk to the fibrous expansion of the extensor tendon at the side of the finger. A short strip of tendon may be laid in the same way across the profundus opposite the middle of the proximal phalanx and sutured to the fibrous tissue on either side to form a retaining ligament opposite the point of greatest stress (Fig. 25).

If the deep tendon alone has been divided beyond the point of insertion of the flexor sublimis (Fig. 29) suture may be rendered difficult because the distal stump is short and almost inaccessible for accurate suture from a lateral incision. It is in such cases particularly that an incision in the shape of an inverted L, (1) with its transverse limb at the distal flexion crease of the finger, may be helpful. In such cases one must also be certain that the remains of the fibrous tendon sheath does not form a

barrier to the full movement of the tendon as it is drawn upward by contraction of the flexor muscle or that the new annular ligament if one is provided does not form a similar obstruction.

Finally after tendon repair is completed the digital nerves, if they have been divided are united by end to-end suture.

INJURIES OF THE DORSUM OF THE HAND (Figures 5 28 30, 31 32 33)

While injuries of the dorsum of the hand with division of the tendons and nerves may occur at any point the majority of them are included in one of four groups: (1) injuries on the dorsum of the wrist with division of the extensor tendons of the four fingers; (2) injuries on the radiodorsal surface of the wrist with division of the long abductor of the thumb and the extensors of the thumb and wrist; (3) injuries on the dorsum of the metacarpus; and (4) subcutaneous rupture of the extensor tendon opposite the distal interphalangeal joint. With tendon injuries included in the first three groups there may be division of one or more of the sensory branches of the radial or ulnar nerves.

Injuries on the dorsum of the wrist frequently result in a division of the extensor

digitorum communis with or without concomitant division of the extensor indicis proprius, extensor digiti quinti proprius and extensor carpi ulnaris (Fig. 31). The fact that the first of these passes underneath the dorsal carpal ligament through the same compartment as the extensor digitorum communis makes it almost inevitable that it should be injured if the common extensor is divided. Common characteristics of these injuries are the marked retraction of both segments of the divided tendons and the fact that usually both proximal and distal segments are firmly matted together by scar tissue for some distance from the point of division. Since a muscle relieved of its normal tension immediately contracts to the resting stage, the proximal segments of the divided tendons retract upward into the forearm. Because the flexor muscles are more powerful than the extensors and since the normal position of the relaxed hand is with the fingers in semiflexion, the distal segments of the divided tendons are drawn distalward with the result that the gap between the divided ends is even greater than it is ordinarily after tendon division. Too often the advantage of splinting the injured hand in the position of dorsal flexion immediately after injury has been overlooked and an additional degree of avoidable separation has taken place.

In the operative exposure of such injuries a crescentic or a flap incision (Fig. 29) with its center opposite the site of injury has several advantages. It permits one to lay a flap of fairly normal skin and subcutaneous tissue over the sutured tendons. It may make it possible to avoid entirely cutting across the healed scar and so make more certain primary healing of the operative wound. It facilitates closure of the incision when the wrist is held in dorsal flexion. If on the other hand one makes a vertical incision along the midline of the forearm and directly across the scar, dorsal flexion of the wrist forces the edges of the incision apart and renders closure of the wound extremely difficult. Too often such an incision fails to heal at the site of greatest tension where the operative incision crosses the scar of the original injury; the wound begins to gape, and tissue necrosis and wound infec-

Figs. 29 and 30. Left, nerve injuries of right upper extremity; right, nerve injuries of left upper extremity. In these cases, either a nerve only was injured, or the coincident tendon injury had been repaired elsewhere at the primary operation.

tion take place, with the result that healing is delayed and the ultimate result definitely impaired.

In making the operative incision and raising the flap it is necessary to remember that the sensory nerves lie just underneath the subcutaneous tissue, superficial to the deep fascia overlying the tendons. As in operations elsewhere on the hand the nerves must be recognized and isolated at the outset of the operation or they will be irreparably injured.

Before the divided tendons can be united it is necessary to free them from the surrounding scar tissue to such an extent that a pull applied directly to the proximal segments draws them well down into the field of operation, and a pull applied to the distal segments

Fig. 40. Division of flexor pollicis longus. Tendon suture 48 hours after operation followed by infection of tendon sheath and radial burn. Result 4 years after operation.

produces complete extension of the affected fingers. It is not necessary and usually not wise to separate the tendons from one another and unite them individually they would simply become adherent to one another again. The operation moreover would be prolonged and rendered more difficult for the individual tendons are so narrow and slender that their approximation is much more difficult than that of a larger tendinous mass.

Injuries on the radiodorsal aspect of the wrist may cause a division of the abductor pollicis longus and extensor brevis, of the extensor pollicis longus alone, of all three tendons or of the three tendons and the underlying extensors of the radius (Fig. 30). If one remembers that the first two tendons pass under the dorsal carpal ligament through the compartment farthest to the lateral side and form the most marked prominence on the lateral aspect of the wrist, that the extensors of the radius pass through the next compartment and at a slightly deeper level and that the extensor pollicis longus passes through a third compartment still more medial and more superficial than the second, it is easy to understand why certain tendons are likely to be divided in certain types of injury either alone or characteristically in association with other tendons. If one keeps in mind this association he is not likely for example, to fail to find and unite the divided extensor brevis if the abductor longus has been divided or to look for injury of the extensors of the radius if the three more superficial tendons have been divided.

Injuries on the dorsum of the metacarpus may involve one or more of the extensor tendons of the fingers (Figs. 5-31). Because the individual tendons are united laterally by the oblique bands which pass between them and held to a slight extent by the areolar tissue which surrounds them retraction of the divided tendons is not so marked as after injuries on the dorsum of the wrist, for example and suture of divided tendons on the dorsum of the metacarpus is relatively easy. If after operation the fingers are supported on a cock-up splint, so that there is no tension upon the line of suture for a period of from ten to fifteen days, one should secure a perfect result in practically every instance.

Subcutaneous rupture of the extensor tendon opposite the distal interphalangeal joint (Fig. 33) was discussed by Mason in a paper published in this journal in March, 1930 and the operative treatment carefully described. As Mason pointed out the site of rupture is usually just opposite the joint. In cases seen immediately after injury the tendon may appear intact when first exposed, because the thin sheath of areolar tissue which surrounds the tendon is stretched but not divided. When this sheath is dissected free the ruptured tendon is exposed. In cases seen some time after injury the ends of the tendon are united in a lengthened position by a bridge of connective tissue which has formed within the sheath of areolar tissue. We have secured the best results by excising this thickened connective tissue and bringing the clean cut tendon ends into accurate apposition. If one simply divides

Fig 41a.

Fig 41b

the bridge of connective tissue and overlaps the two segments sufficiently to shorten the lengthened tendon suture is more easily carried out but a considerable mass of tissue is left under the thin skin of the distal phalanx which may interfere with healing of the skin and leave a tender and unsightly swelling at the site of suture.

In excising the bridge of connective tissue that has formed between the ends of the ruptured tendon, care must be taken to leave the greatest length possible attached to the distal phalanx. It is always difficult to be certain that the sutures inserted in the thin distal segment of tendon will not cut through and release their hold on the distal phalanx. The larger the slip of tendon left attached to the distal phalanx the less likely is this to happen.

In the after care of such injuries we have found it wise to splint the affected finger in complete extension or slight hyperextension at the distal interphalangeal joint for a period of two and one half or three weeks. For this purpose the familiar baseball splint of Lewin is very useful.

RÉSUMÉ OF CASES OF DIVIDED NERVES AND TENDONS

Since March, 1916 we have had the opportunity of operating upon 170 patients with division of the nerves and tendons of the hand.²⁵ Ninety-seven of these were from the service of Drs. Kanavel, Loyal Davis, Mason, and Koch at Wesley Memorial Hospital, 57 from the service of Drs. Mason and Koch at

Fig 41. Division in automobile accident of median nerve and all flexor tendons over volar surface of left wrist except deep flexor of little finger. Primary suture of nerve and tendons followed by severe spreading infection and extensive destruction of superficial and deep tissues.

Fig 41c.

Passavant Memorial Hospital, and 16 from the service of Dr. Koch at Cook County Hospital. In 70 cases tendons alone were divided in 31 cases nerves alone, in 69 cases both nerves and tendons.

In 134 cases the injury involved the volar surface of the forearm, wrist or hand, in 37 cases the dorsal surface. (In one patient the dorsal surface of the right hand and volar surface of the left were involved in the same accident.) The hand involved, the approximate location of the various injuries, the relative frequency of injury in different locations, and the relative frequency of associated nerve and tendon injury in different locations are indicated in Figures 34 to 39. The striking fact illustrated by these diagrams is the frequency of involvement of the volar surface of the wrist, the extent of such injuries, and the almost constant association of multiple ten-

²⁵ This does not include a group of 15 cases of nerve and tendon division in which it was impossible to approximate the divided tendons and in which the defects were bridged with tendon grafts.

Fig. 42 Division of ulnar nerve and blood vessels, flexor carpi ulnaris and superficial flexors of four fingers; immediate ligation of blood vessels and suture of divided nerve and tendons under gas and ether anesthesia. Low grade infection of wound with abscess formation persisting for 6 months after operation. Result 8 1/4 months after operation.

don divisions with division of the median or ulnar nerve or both.

The age of the patients varied from 12 months to 60 years. Fifteen were between 1 and 5 years of age, 18 were in the first decade of life, 22 in the second, 63 in the third, 38 in the fourth, 22 in the fifth and 6 in the sixth; the age of one is unknown.

A brief discussion as to the immediate cause of injury, the immediate treatment rendered and the immediate results obtained may be of some interest. In 166 cases the cause of injury was recorded. In 46 cases the injury resulted from a glass cut and in the majority of these cases the patient had fallen and

pushed his hand through a glass door or window. In 25 the injury resulted from an automobile accident and in the majority of such cases it was stated that the wound was caused by broken glass from a windshield or car door. In 23 cases the injury was due to a knife cut, a stab wound or razor wound. In 11 cases the injury resulted from a fall on a bottle, a glass tumbler or a cup with collapse of the object and a resulting penetrating wound. In 9 cases the injury resulted from collapse of the porcelain handle of a water faucet with subsequent laceration and penetration of the palm by a sharply pointed or jagged fragment of the handle. In 12 cases tendon

Fig. 43 Division of median nerve, long flexor tendons of thumb, index and middle fingers, immediate tendon suture elsewhere, primary union, unsatisfactory functional

result with inability to flex thumb and index completely or forcefully. Secondary nerve and tendon suture 5 years after injury. Result 17 years after secondary operation.

division was the result of subcutaneous rupture, in 2 cases the flexor tendon of a finger was involved, in 10 cases an extensor tendon opposite a distal interphalangeal joint. Other causes included gunshot and bullet wounds, injuries from rip saws or circular saws, lacerations from jagged steel fragments, wire sharp edges of zinc and tin and crushing injuries.

Twenty-two patients were seen by us within from 10 minutes to 25 hours of the injury and were operated upon immediately. Two other patients, one seen 36 hours after injury and one 48 hours after injury, were also operated upon immediately. Of these 4 patients the operative wound healed by primary union in 15 cases, wound infection developed in 7 cases, 2 patients did not return after operation and no record of the postoperative course in these 2 cases is available.

The 7 cases in which wound infection developed after immediate operation deserve particular consideration for it was primarily because of the infection which took place in these cases and the severity and duration of the infection in 4 cases (Cases 1, 3, 4, 5) that we were forced to recognize the danger of immediate operation for divided nerves and tendons and that we have since laid so much stress on the importance of delaying repair of divided nerves and tendons unless one is certain that the wound is clean.

CASE 1. F. P. Wesley Memorial Hospital 111566 April 10-May 6 1924 (Fig. 40)

This patient, a bottle inspector 33 years of age, sustained a cut across the volar surface of the thumb at the level of the metacarpophalangeal joint from a broken glass jar April 8 1924. He received treatment from a physician for two days and was then sent to the hospital because of inability to flex his thumb at the interphalangeal joint. He was operated upon under local anesthesia shortly afterward, approximately 48 hours after the injury. The somewhat ragged skin wound was enlarged, the ends of the divided flexor pollicis longus brought together with silk sutures and the skin wound loosely closed with silkworm gut and skin clips. Warm wet dressings were applied to the hand continuously after operation.

The morning after operation April 11 the patient's temperature had risen to 102 degrees and it was noted that there was edema, redness and tenderness, particularly about the wrist and on the radial side. No pain on extension of the little finger, some pain and wincing on extension of the index and

middle fingers. On April 12 swelling of the wrist a little more marked. On April 13 swelling of the wrist forearm and dorsum of hand more marked, redness and exquisite tenderness on radial side of dorsum of wrist. Between April 11 and April 14 the irregular temperature ranged from 98.6 to 103 degrees, reaching the latter point on the afternoon of April 14. April 15 under nitrous oxide anesthesia the radial bursa was opened by extending the operative incision upward for 3 inches along the radial side of the forearm. A thin sanguino-purulent discharge was evacuated which showed a pure growth of staphylococcus (the report does not say whether albus or aureus) on culture. The following day it was noted. Thin seropurulent discharge around rubber tissue drain. Patient feels much better, slept for first time last night.

The infection gradually cleared up and the patient left the hospital May 6, 6 days after operation (tendon suture) with the wound healing but still requiring dressings.

CASE 2. V. H. Wesley Memorial Hospital 113006 114522 July 1, 30 1924 September 19-23 1924

This patient, a 33-year-old carpenter, received a long oblique deep cut of the left palm and wrist from a rip saw June 30. He was taken immediately to a hospital where the injury was treated and the wound sutured under ether anesthesia.

The following day he was transferred to Wesley Memorial Hospital and operated upon under gas and ether anesthesia shortly after admission. The wound, extending from the cleft between the little and ring fingers to the base of the thenar eminence, was opened widely, the median nerve, all the long flexor tendons of thumb and fingers and the first metacarpal bone had been divided, no attempt had been made at operation the day before to repair these structures. The tendons and nerve were united and the hand splinted so as to immobilize the first metacarpal. The operation required 2 hours 5 minutes. Warm wet dressings were applied to the hand at the close of the operation and maintained continuously for 48 hours.

The afternoon following operation the patient's temperature rose to 101 degrees, thereafter it gradually receded, reached normal on the third postoperative day, and did not rise above 99.2 degrees thereafter. Although he complained of some pain in the hand there was very little postoperative swelling and for some days it appeared as though healing were taking place without infection. On the tenth postoperative day, July 12, a slight wound discharge appeared between the little and ring fingers, two sutures were removed from this area and some thin seropurulent discharge escaped. The following day the dressings were fairly well saturated and it was noted that there was separation of the skin edges along almost the entire extent of the wound. Bridges of adhesive were placed across the incision to prevent further separation, the wound was carefully dressed each day and by July 19 there was little

wound discharge. July 25 it was noted that there was still slight wound discharge at the base of the thumb. July 28 the wound was dry still edema on the dorsum of the hand 20 days after operation.

The patient left the hospital July 30, and returned daily for physical therapy. Sometime after leaving the hospital (the exact date is not recorded) a sinus appeared at the distal end of the wound between the ring and little fingers. Because of this he re-entered the hospital September 18. The sinus was curetted and warm wet dressings applied for 48 hours. He left the hospital September 23 and the wound discharge ceased completely shortly afterward.

CASE 3 U. S. Wesley Memorial Hospital, 124311
133054. March 31-May 24, 1926 July 26-
August 1, 1927

This patient a 16 year old piano student, was admitted to the hospital at 11 p.m. twelve hours after an automobile accident in which she had received a glass cut across the volar surface of the left wrist. The divided ulnar artery had been ligated with silk worm gut immediately after the injury. Operation was performed under local anesthesia the following morning, April 1 just twenty four hours after the accident. There was little swelling about the site of injury at the time of operation and no evidence of infection in the open wound. The median nerve and all the flexor tendons over the volar surface of the wrist except the deep flexor of the little finger had been divided. All were isolated. The wound was enlarged by a longitudinal incision, and the divided structures carefully sutured.

Twenty four hours after operation the patient's temperature had risen to 103.6 degrees and her pulse to 140. She complained of some pain in the forearm. The following day the fever and rapid pulse persisted, the forearm was very painful, and considerably swollen. The skin chips and a part of the dermal sutures were removed with the escape of a small amount of thin fluid. Culture of the fluid showed a mixed growth of staphylococcus albus and a short chain streptococcus. After removal of the sutures massive warm dressings were applied to the entire upper extremity.

During the five days following the patient was seriously ill with high fever vomiting and obvious toxemia. Her temperature ranged from 99.4 to 101.4 degrees, her pulse from 112 to 144. On the seventh day after operation the symptoms of acute infection began to subside and as they did so wound discharge became more profuse and necrosis of the tissues about the wound became apparent. Although by this time all sutures had been removed and the wound lay widely open, extension of the infection both upward and downward gradually took place necessitating incision and drainage of the upper forearm April 17 of the thenar space April 23, and of the lower part of the arm above the elbow May 4. May 5 because of considerable loss of blood the day before and because of her critical condition she was given a transfusion of 700 cubic centimeters of citrated blood.

From that time on she improved rather rapidly and left the hospital May 24 eight weeks after the injury with the hand and forearm nearly healed.

During the summer of 1926 she received intensive physical therapy with some improvement in mobility of the fingers.

She was readmitted to the hospital July 26, 1927 a year later. At that time there was definite hypoaesthesia throughout the area of median nerve distribution. The thumb was held in flexion at the interphalangeal joint. The other fingers could be completely flexed, but not completely extended (Fig. 41). At operation July 27 it was found that the suture of the median nerve and the flexor pollicis longus had given way and these structures had become firmly adherent to one another and to the surrounding tissues. The deep tendon to the index finger had healed in a lengthened position. The tendon of the thumb and the median nerve were freed and the ends of each united by end to end suture. The deep tendon of the index finger was shortened.

The range of movement of the hand and fingers and the persistence of atrophy of the thenar muscles August 8, 1926 are shown in Figure 41. At that time sensation to light touch and pin prick was present over the entire median nerve area but somewhat diminished.

CASE 4. U. S. Wesley Memorial Hospital, 127871, 130043, 129315. September 9-16, 1926 December 30-23 1926 February 8-12 1927 (Fig. 42)

This patient, a clerk of 26 years, fell as he was leaving his place of work at 5 p.m. September 9, 1926 his left arm shot forward as he fell and crashed through a plate glass door. He was taken to Wesley Memorial Hospital immediately and operated upon shortly after admission under gas and ether anesthesia. The record does not state the exact time of operation, but does state that he returned from the operating room to the ward at 7:30 p.m.

At operation it was found that the ulnar nerve and blood vessels, the flexor carpi ulnaris, and the superficial flexor tendons of the four fingers had been divided. The ulnar vessels were ligated, the divided nerve and tendons sutured.

The morning after operation the patient's temperature was 100.4 degrees. It fell to 99 degrees the following day and remained normal after the third day. On September 14 it was noted by Dr. Mason, "Some discharge from the wound. This is due, I think, to the tincture of iodine which was swabbed liberally in the wound at the time of operation. Temperature normal." On September 16 the patient left the hospital. There was "slight drainage from the wound, not purulent." The exact date of healing is not recorded.

December 20 the patient was readmitted to the hospital because the wound had opened spontaneously several weeks after healing had taken place and discharge from the resulting sinus had persisted. On admission there were several apparently superficial discharging sinuses along the operative incision.

A drop or two of yellow pus could be expressed from them. These sinuses were excised under gas and ether anesthesia and three pieces of knotted suture material removed from the depth of the rather superficial wound. The wound was loosely sutured. The patient left the hospital on the third day.

February 8 1927 he was readmitted to the hospital with a small discharging sinus still present at the site of the former operation. Because he had a rather severe acute upper respiratory infection no operative procedure was carried out at that time and he left the hospital 4 days after admission. The record does not state the exact time of healing but shows that it was complete April 21 1927 at the time the photographs (Fig. 42) were taken.

CASE 5 H. D. Wesley Memorial Hospital 130406 (Fig. 5)

This patient a girl of 8 years sustained a jagged wound of the dorsum of the left hand from a broken mirror March 12 1927. She was taken immediately to a doctor who dressed the hand and advised hospital care.

She was admitted to the hospital 2½ hours after the injury and operated upon under ether anesthesia an hour later. The wound lay directly over the middle of the metacarpus a triangular flap of skin with its apex above and its base just proximal to the metacarpophalangeal joints had been torn downward the extensor tendons of the index and middle fingers had been completely divided that of the ring finger partially divided. The wound was cleansed in the operating room with soap and water ether alcohol and picric acid solution. The tendons were sutured with silk the wound edges loosely approximated with interrupted sutures and some strands of silk worm gut left in the wound for drainage. The operation, according to the anesthetist's record required thirty minutes. Warm wet dressings were applied to the hand at the close of the operation and maintained for the next 9 days.

March 14 48 hours after operation the patient's temperature had risen to 102 degrees. The following day March 15 there was considerable swelling of the flap three sutures were removed from the skin and a small quantity of seropurulent fluid escaped from the wound. On the fourth day March 16 a Carrel tube was inserted into the wound and instillation of 3 cubic centimeters of Dakin's solution every 3 hours begun. The warm boric dressings were continued as before. March 18 considerable pus was expressed from the wound the patient's temperature had gradually receded from 102 to 100 degrees. March 20 the instillation of Dakin's solution was discontinued. March 22 the continuous warm wet dressings were discontinued and instead the hand was soaked for 15 to 20 minutes twice daily in warm sterile boric solution.

The infection cleared up very slowly. April 15 a small localized accumulation of pus under the healing flap was incised and continuous warm boric dressings again applied for 2 days. The wound was almost healed when the patient was discharged from

the hospital May 3 1927 7½ weeks after admission. In spite of the prolonged suppuration and the prominent scar on the dorsum of the hand the functional result was excellent (Fig. 5).

In the last case the possibility of chemical injury of the tissues about the wound comes into consideration as mirror glass injuries in other cases in our experience have been followed by persistent suppuration with slow but progressive necrosis of the surrounding tissues. Whether it was a factor in this case is of course purely conjecture.

Of the 146 patients who came to us for secondary treatment an immediate closure of the superficial wound alone had been carried out elsewhere in 42 cases. In 22 of these cases the wound healed by primary union in 6 cases there was a slight wound discharge for from 2 days to 3 weeks. In 10 cases suppuration developed. In 4 cases there is no record as to the immediate result.

In 54 of the 146 cases immediate nerve and tendon suture had been carried out elsewhere. In 28 of these the wound healed by primary union, in 8 a low grade infection developed, in 14 suppuration and tissue necrosis took place and complete wound healing was delayed for from 3 to 10 weeks from the time of injury.

In 146 of our cases in which secondary operation was performed i.e. all the cases except the group of 24 operated upon by us shortly after the injury the operative wound healed by primary union in 119 cases. In 3 cases there is no record as to the result as far as infection is concerned. In 4 cases failure of primary union was due to slow necrosis either of a longitudinal strip of skin along the line of incision or of a small transverse section of skin centering at the site of the original transverse wound. This necrosis we believe resulted from impairment of the blood supply of the skin flaps, either because of scar tissue formation following the original injury, because of trauma during the operation, because of excessively thin skin flaps, or because the skin was sutured under excessive tension.

In 20 cases of secondary operation failure of primary union was due to infection. In 8 of these infection was described as "slight, low grade, superficial infection of center of

wound etc., and cleared up in from 10 to 24 days after operation. In 4 infection was slight but persistent or recurrent for from two and one-half to six months after operation and subsided when some unabsorbed suture material was extruded. In 8 suppuration developed with some necrosis of superficial and deeper tissues, and complete healing was delayed for from four to eight and one-half weeks after operation.

The incidence of postoperative infection has become steadily less. In 63 out of 71 cases operated upon between June 1929 and July 1932 the operative wound healed by primary union. In 3 of the 8 which did not heal by primary union there was slow necrosis of a strip of skin along the line of operative incision without evidence of infection until this necrosis took place. In 3 the infection was slight and cleared up in from ten to eighteen days after operation. In 1 infection was apparently due to organisms of low virulence but a slight discharge persisted for eight weeks after operation. In 1 frank suppuration and sloughing of tissues took place and healing did not take place until eight and one-half weeks after operation. In spite of the fact that we have not yet succeeded in eliminating infection as a postoperative complication we believe that it is avoidable and that it can be eliminated by watchful care at every stage in the operative treatment from the beginning of the preparation of the hand for operation to the time of removal of sutures.

RESULTS OF SUTURE OF DIVIDED NERVES AND TENDONS

A number of factors conspire to make difficult an appraisal of the results obtained in a group of cases such as that under discussion. The ambition of the workman to secure a good result, the desire of the patient to show a satisfactory result, or occasionally his desire to minimize the degree of improvement because of the possibility of securing additional compensation, the location and extent of the original injury, the interval of time elapsing between the injury and the operation, the amount of scar tissue formation present at the time of operation which is usually directly dependent upon the extent and character of

the infection which followed the original injury, the time that has elapsed between the operation and the last examination—an essential consideration in the case of nerve suture and the faithfulness with which physical therapy, exercise and use of the injured hand have been carried out. Because of these many factors affecting each case in varying degree it is almost impossible to classify the results obtained as excellent, good, etc. If a patient secures a usable and useful hand after a severe injury and serious infection that have resulted in complete loss of function for a year or more such a result can fairly be considered excellent, though the hand may be far from perfect as compared with the normal. On the other hand if one secures a result somewhat less than perfect in a case in which every condition has been favorable, it can not truly be considered an excellent result. The results of nerve suture particularly are difficult to interpret.²² The rapidity with which overlap from adjacent nerves develops in the area supplied by the divided nerve varies in different individuals and as has been stated above this one factor emphasized particularly by Pollock, is a constant possible source of error in interpreting the findings present after nerve suture. The patient's interpretation of the signs of returning sensation is often misleading and one must be conservative about drawing conclusions simply from a patient's statement (Fig. 14).

We have not been able to secure results such as Bunnell has obtained—return of sensation at the rate of a phalanx a month after suture of the digital nerves—nor have we seen return of function appear as rapidly in the majority of cases as is suggested by most writers to be the normal expectancy. On the other hand we have seen progressive improvement taking place for a long period after operation and continuing far beyond the time ordinarily considered as marking the limit of possible improvement. We say ordinarily considered, although we do not know of any accurate statements concerning the length of time during which improvement can be expected to continue after nerve suture. In this

²² "The prognosis of nerve suture is a matter of great complexity and the term 'recovery' as so relative as almost to cause to have means beg. Swartz and Trueman.

connection the following case report is of particular interest, and especially so because the patient is a physician and accustomed to making accurate observations

R. A. Wesley Memorial Hospital 50951 (Fig. 43)

This patient, a 29 year old medical student at the age of 1, plunged his right hand through a glass window and divided the median nerve and long flexor tendons of thumb index and middle fingers. The tendons were sutured soon afterward the wound healed without infection. After the accident complete anesthesia in the median nerve area persisted the skin became somewhat atrophic and gross changes in appearance and brittleness appeared in the nails of thumb index and middle fingers. Atrophy of the thenar muscles was slow but progressive. There was impairment of flexion of the thumb and complete loss of flexion of the index finger.

December 19, 1914, 6 years after the accident nerve and tendon suture were performed by Dr. Kanavel. At operation it was found that the proximal segment of the median nerve had become united to the distal segment of the flexor pollicis longus. Nerve and tendon were separated and an anatomical restoration carried out. The patient was discharged from the hospital 5 days after operation postoperative recovery was complicated by persistent serous drainage from a small sinus. Complete healing took place after a piece of unabsorbed catgut was removed from the wound.

January 8, 1932, the patient stated. Sensory change following the operation was very slow in appearing. There was very little change at all during the first year but progress in both sensation and cutaneous trophic changes was progressive after three years. In fact I believe that there was as much change after three years as there was before.

"The hand gradually improved year by year and apparently has improved not only in appearance but in sensation even in the last few years.

As you know from the last examination there is now very little difference in the palmar surface of the two hands and the only sign of trophic disturbance is that the skin along the ulnar side of the thumb nail is rough and indurated. Otherwise the nails appear practically normal. There are still a slight perceptible roughness and lack of markings in the radial one-half of the palm. The thenar atrophy has never improved. All function is present in the hand and I am able to flex the fingers completely with the fingers in full extension at the metacarpophalangeal joints. I operate with this hand, use the scalpel, and have normal use in the fingers (Fig. 43) except that I do miss the opponens action.

Another fact should be recorded which concerns particularly the results of tendon suture but which applies to patients with nerve suture as well. Division of tendons and nerves is

followed by retraction and atrophy of the divided tendons and muscles and atrophy of the muscles innervated by the divided nerves. Its extent depends to a considerable degree on the interval elapsing between the injury and the reparative operation. When the divided tendons are united movement is again made possible but such movement at first is often sluggish and definitely limited. With use however even though it is minimal at the outset the atrophic process is arrested and the cycle is reversed. Use of the part stimulates blood supply and muscle and nerve regeneration. Muscle and nerve regeneration and return of motor nerve function permit a little greater use and movements of greater range and power. In other words the reversed cycle becomes a beneficent one instead of a vicious one and each phase re-enforces the other. The result is that patients who have gained only a limited restoration of function at the end of a few months often return after a year or eighteen months with a surprising and sometimes unexpected degree of improvement.

We believe we can say fairly that the results of operation have justified the efforts the time and money which the patients have expended in the attempt to secure improved function and secondly that our results have definitely improved with increasing experience and increasing efforts to secure healing by primary union and without infection. A few patients have secured a perfect functional result and it is such cases particularly that encourage us to keep on trying to perfect our technique to such a point that we can in fairness hold out to every patient with division of nerves and tendons the reasonable assurance of a satisfactory result.

SUMMARY

In the treatment of divided nerves and tendons a careful examination of the patient before operation to determine the degree and extent of injury is of primary importance. To choose the wisest plan of immediate treatment requires careful consideration of a number of factors, unless one can be reasonably certain that the wound is free from infection it is far better to leave the superficial wound

open or suture it loosely and permit it to heal than to run the risk of opening tissue spaces widely and bringing about widespread extension of a virulent infection.

When operation is performed whether immediately or at a later date, every effort should be made to ensure healing by primary union for in securing a successful result nothing in the way of accurate apposition, careful suture or painstaking postoperative care can compensate for failure to secure wound healing without infection.

In the technique of operation gentleness in the handling of tissues, accurate apposition of tendons, end-to-end apposition of healthy nerve ends, the use of fine suture material and the employment of a bloodless field during the operative procedure are important details. Properly designed splints and skillfully applied physical therapy are important and helpful adjuncts in securing successful results in the shortest possible period of time after operation.

OBSERVATIONS ON THE MECHANISM AND SIGNS OF SEPARATION OF THE PLACENTA

LOUIS DROSIN, M.D. NEW YORK, NEW YORK.

Attending Gynecologist, Beth David Hospital; Chief, Gynecological Department, Beth David Dispensary

SINCE 1914 the author has been practicing as a matter of routine a method of facilitating separation and delivery of the placenta, which has met all indications, although, since it involves considerable inconvenience in maintaining asepsis it is now employed only in cases in which there is lack of contraction of the uterus, bleeding or adherent or retained placenta. This method (2) was original with him and was named by him the dorsosquatting posture suggested by the posture assumed at stool by primitive peoples (3). It is an evolution of the one called exaggerated lithotomy position which DeLee advocated in cases of inefficient pains and in moderately contracted pelvis, at the end of the first and the beginning of the second stages of labor (1). Figure 1 shows the dorsosquatting posture with pelvis suspended. Figure 2 the dorsosquatting posture in action during the third stage of labor. In this all the pelvic diameters are increased the rectus muscles contract and harden intra-abdominal space is diminished and intra-abdominal pressure is increased. Uniform continuous pressure on the uterus causes correspondingly regular contraction and retraction. The sinuses empty the blood vessels regain their tonicity to some extent and the uterus thus contracts retracts and remains firm. This is accomplished in 6 or 7 minutes but the posture is maintained for a few minutes longer at which time the placenta is easily expelled intact and with comparatively little free loss of blood. The posture is continued for another short period to insure the contraction and involution of the uterus.

SIGNS OF SEPARATION OF THE PLACENTA

Thus far the only reliable sign indicative of separation of the placenta is a firmly contracting uterus, all other so called signs being only theoretically incidentally or occasionally true. Dr Morris Levi from observations on a

thousand cases, finds that the placenta separates completely soon after the uterus is reduced in size and that separation occurs from 2 to 5 minutes after tying the cord or a maximum of 8 or 9 minutes after delivery of the fetus. He comes to this conclusion after digital examination of the vagina when he finds the placenta at the level of or somewhat lower than, the external os.

The author considers the placenta separated only when it is lying freely in the vagina. Otherwise, it is only partly separated, being still sustained by part of the placenta or the undetached membranes and these membranes are almost as likely as the placenta proper to give trouble both during and after delivery. Even in the Schultz method when the bulk of the placenta can be felt at the lower edge of the cervix or upper end of the vagina it may still be upheld by undetached membranes or by all or part of its normally most adherent position—the circular edge. Even the size of the placenta thus palpable is but relative since at this time all the diameters of the uterus are diminished and the passive lower segment, drawn up to the higher level, exposes to palpation a larger area of placenta regardless of the extent of separation, a condition more marked in low implantation of the placenta. This area may be still further increased by the resiliency inherent in the placenta, which causes it to accommodate itself to a contracting uterus without separation but with the formation of a convex bulge.

Recent observations show that in normal cases the placenta presents itself at the level below the dilated external os usually after the third fourth or fifth regular contraction exclusive of the initial contraction following delivery. Occasionally the placenta will separate after the first contraction if this is strong and prolonged. It descends and becomes tense with each contraction and rises and

Fig. 1

softens during relaxation. If the contractions are more pronounced than the relaxations the placenta will progressively descend without rising and softening during the intervals. Normally the internal os or contraction ring forms immediately after expulsion of the placenta to the extent of diminishing the lumen of the lower segment of the uterus to a diameter varying from one half to one and a quarter inches with the soft, thin and relatively shrunken cervix below and in front of it. Soft and ill-defined ring formation before the descent of the placenta is not infrequent, but if expression is not forced or hurried it will yield sufficiently to allow its passage and then immediately recontract. Two cases were observed in which the cervix consisting at this time normally of a loose soft circular flap before the placenta presented itself at the external os, assumed the form of a number of firm, irregular concentric convexities in horizontal position making up the cervical canal. With the expulsion of the placenta the cervix was immediately drawn up with the convexities in perpendicular co-centric position facing the uterine canal, the vaginal surface thus assuming the aspect of normal cervical mucosa and the external os admitting one finger. Since in neither case could the examining finger feel the usual contraction ring with the soft cervix below and in front of it, the occurrence might be explained on the basis of atypical ring or external os formation.

IRREGULARITIES AT THE PLACENTAL SITE AND POSSIBLE MECHANISM OF ITS OCCURRENCE

In January 1920, while waiting for signs of separation of the placenta the author noticed

Fig. 2.

on irregular area on the uterine wall located sometimes on the fundus sometimes on the anterior and sometimes on the posterior wall having the appearance of multiple shallow subserous fibroids. Further observations showed that in the vast majority of cases except in those in which there was complete hardening of the uterus this sign made its appearance from 10 to 15 minutes after the birth of the fetus which is a little less than the average time it takes for the placenta to separate. While the presence of this sign may not always be an evidence of complete separation of the placenta, it does imply a maximum amount of detachment and more important still a higher degree of contraction and retraction making it safe at this time to attempt expulsion. No difficulties were ever encountered when attempts at expression were made after the appearance of this sign. In the majority of over two hundred cases in which the separation of the placenta was studied by means of palpation with fingers in vagina to a height above the external os the irregularities appeared after the placenta was lying freely in the vault of the vagina. These irregularities can form only at the placental site, which at this time is the most vascular and therefore the most yielding part of the uterus. The following attempt has been made to explain the mechanism of their occurrence.

The pregnant uterus may be compared to a syringe with yielding or collapsible wall, minus an opening for the nozzle and with a piston of two parts the fetus and the placenta. With the gradual dilatation of the cervix, beginning at the establishment of the first stage

of labor the vacuum principle initiated by the contractions and relaxations of pregnancy is set into play. The tendency of the uterus to contract obliterates the vacuum caused by relaxation and forces the fetus downward. The following relaxation creates a new vacuum forcing the fetus upward but to a less degree than the preceding one and the succeeding contraction in its turn continues the downward course of the fetus. When the uterus is sufficiently drawn up above the presenting part to cause this vacuum to become inefficient the abdominal muscles and intra-abdominal pressure readily supplement this deficiency. With the expulsion of the fetus the major part of the piston disappears and the uterus contracts obliterating the vacuum space. The placenta and membranes now become puckered or partly separated with resultant vacuum formation and with the aid of inherent contraction retraction and relaxation and retroplacental blood formation these vacua cause after the placenta is sufficiently separated and the sinuses obliterated by means of compression and aspiration an irregular caving in of the placental site.

The following observation in a general way proves the reality of the syringe vacuum principle which is operative during pregnancy and labor.

Mrs. A. E. 1-para, full term measurements and pregnancy normal delivered of twins on March 14 1930 at Hunt's Point Hospital. First infant occipitoposterior was delivered with forceps. The second, larger infant presented too high for forceps application. With patient still anesthetized podalic version was performed. When legs presented at vaginal outlet, patient's respiration became loudly stertorous and deep and with each respiration the fetus progressively descended until it reached the nipple line when patient's respiration became more normal, and spontaneous progress ceased.

In 2 later cases of breech extraction delivered in private homes the phenomenon was absent in the first, which was a very large

child and present in the second, which was a 6 pound child. There is reason therefore to believe that in the absence of relative disproportion between the parturient outlet and the child this mechanism or its tendency should be manifest.

The same tendency is felt though in reversed order when attempts are made in primiparae to stretch the vagina with the fist previous to operative interference. As soon as the fist passes the hymenal sphincter the upward suction with each respiration can be distinctly felt.

It has further been observed in a number of forceps deliveries at the time the vaginal sphincter engaged the largest diameter of the head, if the forceps were then used simply as a means to prevent its recession the respirations became deep and stertorous and with each respiration progress was made until the sphincter grasp was relieved.

Another illustration of the vacuum principle, which casts light on the mechanism involved in the maintenance of fetal heart action and circulation is supplied by the cutting away of a portion of the cord just below the ligature applied before it is severed and the squeezing out of the blood, starting at the placental end. The cord will immediately refill with the placental blood. This may be repeated for as long a period as 30 minutes and the cord will promptly refill, regardless of the position in which it is held.

POSTOPERATIVE PULMONARY COMPLICATIONS

I. A STATISTICAL STUDY BASED ON TWO YEARS' PERSONAL OBSERVATION¹

DONALD S. KING, M.D., BOSTON, MASSACHUSETTS

THIS study of postoperative pulmonary complications occurring on the General Surgical Services of the Massachusetts General Hospital was begun in the fall of 1929. It was made from the standpoint of the internist and was undertaken at the suggestion of Dr. L. S. McKim, of the Surgical Service. After a preliminary study of the hospital records, it was found that figures from these records were unsatisfactory, since the milder pulmonary complications as a rule were not included in the discharge diagnoses and adequate descriptions of the complications were not recorded. For example, only 44 per cent of the complications occurring in 1929 were listed in the discharge diagnoses. (The remainder were found by a study of the bi-monthly surgical reports or the hospital records and by personal observation.) It was apparent, therefore, that really satisfactory statistics could be obtained only by personal observation during the period for which figures were to be reported. Accordingly, the author observed personally practically all of the postoperative pulmonary complications in 1930 and 1931, and in addition studied a great many cases of the type in which complications most frequently develop although they did not actually occur. The observations have been made carefully, and the figures have been compiled accurately, so that although most of the conclusions are not new, they are based upon a series of cases sufficiently large to make the percentages reliable and they emphasize points which we believe essential to an understanding of the problem.

The nature of the process. The study has been confined to the type of complication which occurs in the first three or four days after operation and is almost always accompanied by fever, leucocytosis, cough, and purulent sputum. Cases of proved pulmonary embolus, exacerbation of pulmonary tuberculosis, empyema, and so forth, have been excluded. The type of complication studied has

been diagnosed in the literature as bronchopneumonia "pneumonitis" or collapse (atelectasis). In the series here reported a certain number of cases have run the clinical course and presented the physical and X-ray signs of a true bronchopneumonia. The percentage of these cases is small; nevertheless the group is important since it includes most of the fatal cases. There is also a much smaller number of cases which can be diagnosed clinically and by X-ray as typical "massive collapse" produced by occlusion of a large bronchus by exudate and clearing quickly when the "plug" is expelled by cough. Between these two definite entities lies a large "intermediate" group of cases which are more difficult to classify.

The lesion in this intermediate group is not "pneumonia" in the medical sense since it runs a much shorter and less toxic course. Whipple (6) has called it "pneumonitis" using that term to mean a "pneumonia" in which the alveolar exudate is caused by a relatively avirulent pneumococcus, is lacking in fibrin, and is therefore quickly absorbed. Cutler has regarded it as exuberant pneumonia but the onset is much earlier than in most proved cases of pulmonary embolus and the symptoms and signs are so different that his theory is difficult to prove. Coryllos has championed the collapse theory, maintaining that the steps in the development of postoperative "pneumonia" are bronchitis, obstruction of a bronchus by exudate, atelectasis due to bronchial obstruction, and then pneumonia developing in the collapsed area.

The differential diagnosis is, then, between low grade bronchopneumonia (better termed "pneumonitis") and lobar or lobular atelectasis. A study of X-rays and physical signs has assisted in the attempt at differentiation.

Dr. G. W. Holmes of our X-ray Department, is of the opinion that those cases in which the X-ray shows increased density with a definite diminution in lung volume on the affected side should be diagnosed as collapse

¹ A study made on the Surgical Services of the Massachusetts General Hospital by the author, a member of the Medical Service.

Fig. Monthly percentage of pulmonary complications following laparotomies and hernia operations in 1930 and 1931 (CO₂ study)

This reduction in volume is shown in the typical case by displacement of the mediastinum, elevation of the diaphragm downward inclination of the ribs and narrowing of the intercostal spaces. All of these signs of collapse are not present in every case. Displaced mediastinum or elevated diaphragm may occur alone. Dr. Holmes calls attention to the danger of making a diagnosis from an X-ray film taken at full inspiration because, at this phase of respiration displacement toward the affected side is present in consolidation as well as in atelectasis. In a true atelectasis displacement toward the side of the lesion is present on expiration as well as on inspiration while in consolidation this displacement is present on inspiration only. Care must be taken also to exclude those films in which X-ray signs might be due to exposure at complete expiration (5). Further it must be remembered that in a bilateral process of any sort there is usually no displacement of the mediastinum.

TABLE I.—CLASSIFICATION

	1928	1929	1930	1931
Collapse	16	25	87	113
"Bronchopneumonia	73	10	152	74
Total	89	35	239	187
Bronchitis	—	142	92	11

The classification of cases in Table I is based largely on X-ray evidence of diminished lung volume. It is interesting to note that as the years have gone on and knowledge of the process has increased, the diagnosis of atelectasis has become more frequent, so that whereas in 1928 less than one fifth of the total complications were diagnosed as collapse in 1931 two-

thirds of the cases were so recorded. Of the 200 cases classified as collapse in the years 1930 and 1931 78 could be diagnosed on the basis of physical signs alone and the other 122 required X-ray evidence of diminished lung volume. (To complete the figures, the number of cases of bronchitis without parenchymal involvement has been added to Table I.)

The study of physical signs has become increasingly important because of the stress which has been laid upon bronchial obstruction as a factor in the production of postoperative pulmonary collapse. Dr. Frederick T. Lord of this hospital, has made a study of the physical signs which occur with bronchial obstruction and has repeatedly shown that obstruction of a bronchus from any cause gives dullness and absent or much diminished breathing (without bronchial breathing) and absent or diminished voice (without egophony) and diminished whisper and tactile fremitus. If however the bronchial obstruction is removed and the atelectasis persists, the signs change and are those of consolidation. It is especially important to call attention to the signs of atelectasis with open bronchus because many authors have assumed that when bronchial breathing appears over a collapsed area, a true pneumonia has unquestionably developed.

If one is to accept the theory that most postoperative pulmonary complications are atelectases due to occluded bronchi the first signs should be very much diminished or absent breathing which, when the bronchus is open, should change to bronchial breathing and the other signs of consolidation (unless the lung expands immediately). In some cases

(16 of our 1931 series), this progression of signs did take place and it is possible that very frequent examinations started soon after the operation would show it in most cases. Actually in 1931 140 of 187 pulmonary complications showed definite changes in breath sounds. Of these diminished breathing was the first change noted in 66 cases and bronchial breathing was the first change in 74 cases. These groups ran practically the same clinical course and it was impossible to say that diminished breathing at the first examination indicated collapse while bronchial breathing at this time indicated pneumonia. Forty five of the 66 cases with diminished breathing at first examination and 44 of the 74 cases with bronchial breathing were eventually diagnosed as collapse. Physical examination therefore except when it shows definite mediastinal displacement is of little value in separating pneumonia from collapse. The important point to remember is that bronchial breathing may indicate either pneumonic consolidation or an atelectatic area with open bronchus. (In interpreting physical signs, it should be borne in mind that an elevation of one side of the diaphragm which frequently follows abdominal operation will often account for diminished breathing at the base without the presence of atelectasis.)

Table I shows the large number of cases of bronchitis in which the X ray has shown no parenchymal involvement. Many of these cases ran the same clinical course as those in which portions of the lung were involved. We believe, therefore, that a purulent bronchitis develops in a large percentage of postoperative cases, that in some cases the infection is limited to the bronchi, and that in the intermediate group of pulmonary complications, now under discussion there is an accompanying "pneumonitis," combined at times with atelectasis due to occlusion of the bronchi by exudate. We have found no evidence that atelectasis necessarily precedes pneumonitis and have been able to prove atelectasis in only 47 per cent of our series of cases. In most instances a sharp distinction cannot be drawn between pneumonitis and collapse. In this intermediate group, the underlying lesion in all cases being purulent bronchitis. (An occa-

sional instance has been observed with "simple collapse," having very little fever and no expectoration.)

As noted in the beginning there is a small group of typical bronchopneumonias which can be clearly differentiated from the intermediate group just described. In 1930 and 1931, there were 30 cases of this type. Eleven of the 13 fatal cases were included in this group and showed from the start a diffuse bronchopneumonic process in the upper as well as the lower lobes and there was no evidence that there had been a preceding atelectasis. In the 2 other fatal cases pneumonia may have developed in an atelectatic area.

Since this is primarily a statistical study the theories of etiology will not be further discussed nor will the considerable literature on the subject be reviewed, both having been frequently and exhaustively presented by other authors.

TABLE II MORBIDITY AND MORTALITY

	1929	1930	1931
Pneumonia and collapse			
In all operations	3.7	6.8	5.2
Laparotomies and herniorrhaphies only	7.7	14.3	11.3
Mortality due primarily to pneumonia and collapse			
In all operations	0.3	0.6	0.4
Laparotomies and herniorrhaphies only	0.9	1.1	0.8
In "pneumonia" and collapse	0.9	8.7	8.6
Mortality all causes			
In "pneumonia" and collapse	33.3	24.3	20.3

Percentage of complications. Table II gives a summary of the percentage of complications with the accompanying mortality incidence occurring on the General Surgical Services¹ in the 3 years 1929, 1930, and 1931. Although the author's routine personal observation of patients did not begin until 1930, a very careful study of every surgical record, in 1929, gives statistics that are of interest for comparison. The figure for incidence of postoperative pulmonary complications following general and abdominal operations is higher than that reported by other authors (1, 3, 6).

Mortality. In the group in which death was "due primarily to pneumonia and collapse" are included those patients whose postopera-

¹In the Massachusetts General Hospital there are special services for genito-urinary, orthopedic, eye, ear, nose, and throat surgery.

TABLE III.—MORTALITY

Complication considered as	Number of patients	
	1930	31
Primary cause of death	5	2
Major contributing cause of death	16	2
Minor contributing cause of death	25	14
No connection with death	12	9
Total	58	38

tive pulmonary complication was either a primary or a major contributing cause of death. It will be noted that although a rather large percentage of patients developing pulmonary complications do not live the percentage of those in whom the complication can be considered as a definite factor in the patient's death is comparatively small. The fact is again emphasized in Table III which analyzes further the group who have had pulmonary complications and have died.

Severity Table II presents the cases grouped according to severity. The cases presenting clinical symptoms and signs of bronchitis, but in which the X-ray demonstrated definite parenchymal involvement, have been classified as mild.

Sex and type of operation The most important factors in the occurrence of postoperative pulmonary complications are type of operation and sex of the patient. The figures for the various types of operation in the two sexes are given in Tables V and VI. These figures bring out the following facts. The incidence of pulmonary complications among men is at least

TABLE IV.—SEVERITY

Severity	Number of patients	
	1930	31
Severe	35	17
Moderate	140	122
Mild	64	43
Total	239	187

twice that among women. Complications are more than twelve times as frequent following laparotomy and herniorrhaphy as after operations in the non-abdominal group. They occur most frequently following operations on the stomach and duodenum, gall bladder and intestines. Therefore the group of men having operations on the stomach and duodenum, gall bladder and intestines has been designated as the "bad risk" group because of their consistently high percentage of pulmonary complications. In the group of non-abdominal operations complications have occurred most frequently after operations on the thyroid. Of 134 patients having thyroid operations in 1930, 10 developed pulmonary complications which gives a percentage of 7.5 and in 1931, 7 of 102 patients or 6.9 per cent, developed complications. It will be noted that of the fourteen complications following non-abdominal operations in 1931, half occurred after operations on the thyroid.

Septis and perforation Table VII gives a further analysis of the cases grouped in Tables V and VI under stomach and duodenum and appendix. The extraordinarily high

percentage of pulmonary complications in men following gastric and duodenal suture is of especial interest, as well as the high percentage of complications occurring in 1930 after gastrostomy alone. That complications do not occur simply as a result of opening the abdomen, but are dependent to a great extent upon the pre-operative condition of the individual patient is well brought out by the analysis of the appendectomy group. The figures show a much higher percentage of pulmonary

complications following appendectomy with drainage than after simple appendectomy or appendectomy with exploration.

Pre-operative respiratory infection. The tables so far mentioned stress the importance of the type of operation and the presence of pre-operative sepsis. In addition the relation of pre-existing respiratory infection to the development of postoperative pulmonary complications has been of interest. Of the 239 complications occurring in 1930, only 16 (10.8

per cent) had pre-operative respiratory infection of an acute or chronic nature. Of the 187 cases in 1931 35 patients (18.7 per cent) had such pre-operative infection. The apparent increase in the 1931 figures is undoubtedly due to the careful recording of pre-operative infections by the nurse in charge of carbon dioxide inhalations.

There are no figures available to show the relation of acute respiratory infection in the community at large to the occurrence of post-operative pulmonary complications in the hospital except those for lobar pneumonia which show that the pneumonia curve is not paralleled by our curve for pulmonary complications.

Monthly incidence. Table VIII and Figure 1 give the percentage of postoperative pulmonary complications by months for the 2 years, 1930 and 1931. Since the incidence of pulmonary complications is so much higher after laparotomy and herniorrhaphy the monthly incidence is computed for this type rather than for the total number of operations. In 1930 there was a definitely higher percentage of complications in the late spring and late fall than during the summer but there is not the marked seasonal variation which has been reported by some authors. In 1931 the highest percentage occurs in January, February and March, with slight elevation again in October and November. Improved methods of bronchial drainage are probably responsible for the lower percentages in the latter part of 1931.

The severity of the complication in relation

to season has been studied and here the figures for the 2 years differ markedly. The severe complications in 1930 occurred predominantly in October, November, December and March—in the winter months. In 1931 almost half of the severe complications occurred in the 4 months, May to August inclusive—predominantly in the summer months.

Anesthesia. Table IX shows the percentage of pulmonary complications occurring after laparotomies and herniorrhaphies under the different types of anesthesia. The figures for 1931 do not include the total operations for the year since they are compiled from a group of cases selected for a special study (4). However they do cover a great majority of the operations performed and are a representative group for the year. (The patients given spinal or rectal anesthesia with supplementary ether are included in the 'inhalation group').

The high percentage of complications occurring in the group which were given spinal anesthesia is of interest and many surgeons have been of the opinion that this high percentage was due to the fact that the poorer operative risks were selected for spinal anesthesia. Consequently an attempt was made to analyze a type of operation in which the pre-operative condition of the patients in the group given ether was as nearly as possible the same as the pre-operative condition of the patients in the group given spinal anesthesia. The male patients with hernias, between the ages of 30 and 60 years operated upon in 1930 were selected as more nearly approximating these requirements than any other group. Table X gives the results and shows a higher percentage of complications after spinal anesthesia in every age group. It is true, however that a further study of the group revealed that of the 66 cases selected for inhalation anesthesia, all were considered good ether risks except 8 who were designated as fair. (Two of these patients had strangulated hernias.) Of the 54 patients selected for spinal anesthesia 19 were listed as fair ether risks and 3 as 'poor risks.' (Four patients were operated on for strangulated hernias.) It would seem from this that the increased percentage of complications after spinal anesthesia is due

TABLE IX.—ANÆSTHESIA

40 to 49 years	2	2	100	17	4	23.5
50 to 59 years	19	2	10.5	4	4	100
Total	60	8	13.3	34	11	32.4

in part to a poorer pre-operative condition of the patient

It is of especial interest to note that in both years the percentage of complications was highest after local anæsthesia. Most of the operations in this group were palliative intestinal operations done for relief of intestinal obstruction due to malignancy. This lends further support to the opinion that the pre-operative condition of the patient is a more definite factor in the development of pulmonary complications than length of operation or type of anæsthesia.

The group of patients given avertin in 1931 is a small series of carefully selected 'good risks'.

Bacteriology In the winter of 1930 a pneumococcus typing was done on the sputa of 44 patients. Of this number the specimens from 14 patients contained very few pneumococci and of the 30 sputa which gave a good growth of pneumococci in the mouse 10 were Type III and the remainder Type IV. At the present time a more complete study of the bacteriology of postoperative pulmonary complications is being made at the Massachusetts General Hospital.

SUMMARY

Statistics based upon 2 years personal observation of the postoperative pulmonary complications occurring on the General Surgical Services of the Massachusetts General Hospital have been presented. Figures have been tabulated separately for the 2 years showing strikingly similar percentages in most instances.

A brief summary combining the figures for the 2 years brings out the following points:

1. Purulent bronchitis develops in a large percentage of patients after operation. In the type of pulmonary complication discussed, bronchitis is associated with 'pneumonitis'. In 47 per cent of the cases there has been sufficient bronchial obstruction to give rise to atelectasis.

2. Eleven of the 13 fatal cases were true bronchopneumonias without evidence of preceding atelectasis.

3. Pneumonia "pneumonitis" or collapse has developed in 6.0 per cent of all operations and in 14.0 per cent of laparotomies and herniorrhaphies and in 7.2 per cent of thyroid operations.

4 The pulmonary complication is regarded as primarily responsible for or as a major contributing cause of death in 0.5 per cent of the total operations performed and in 1.2 per cent of the laparotomies and hernia operations.

5 In practically any given type of operation, the percentage of complications is at least twice as high for men as for women.

6 Among males, the incidence of complications following operations on the stomach and duodenum is 46.8 per cent, on the gall bladder 35.6 per cent, and on the intestines, 26.2 per cent. This group is designated as the 'bad risk' group.

7 Following gastrostomies and palliative operations for intestinal obstruction 22.2 per cent of the patients developed pulmonary complications, and among the patients having gastric and duodenal suture the incidence was 61.8 per cent.

8 After drained appendices 22.5 per cent complications occurred, as compared with 6.6 per cent following simple appendectomy.

9 Of the 426 complications, only 14.3 per cent had pre-operative, acute, or chronic respiratory infection.

10 The seasonal curve does not parallel that for lobar pneumonia or show any consistent seasonal rise.

11 The somewhat lower percentage in 1931 is probably due to better bronchial drainage.

12 In laparotomies and herniorrhaphies 13.7 per cent of the patients operated upon under inhalation anesthesia developed pulmonary complications, 16.6 per cent of those under spinal anesthesia, and 18.4 per cent of those under local anesthesia.

CONCLUSIONS

1 Purulent bronchitis and 'pneumonitis' are present in practically all instances of the type of pulmonary complication here described. Atelectasis is associated with the infection in about one half the cases, but severe and fatal cases are usually true bronchopneumonias without evidence of atelectasis at any stage.

2 Complications occur especially in males following operations on the stomach and duodenum, gall bladder and intestines.

3 Pre-operative sepsis and perforation, as well as malignancy and poor general condition are important factors.

4 Season and pre-operative respiratory infection play a minor part.

5 From the statistical standpoint the type of anesthesia is without significance.

We wish to express our grateful appreciation to the entire Surgical Service and the X-ray Department for their interest and ever ready co-operation.

TWO RAPID TESTS FOR PREGNANCY

J. E. MARKEE, Ph.D., STANFORD UNIVERSITY, CALIFORNIA

From the Department of Anatomy and Physiology

SINCE it has been shown that the rhythmic vascular changes in endometrial transplants onto the iris are arrested by follicular hormone (Markee 1929) the possibility of using that modification of the uterine vascular rhythm as a test for the presence of follicular hormone in the urine of pregnant women suggested itself. Two tests for pregnancy have been devised and their advantages and inherent difficulties investigated. The tests were made in two ways: directly by the injection of follicular hormone that had been extracted from the urine and indirectly by the intravenous injection of untreated urine from pregnant women. The urine of 147 pregnant and 26 non pregnant women has been tested

METHOD OF RECORDING THE RHYTHMIC
UTERINE VASCULAR CHANGES

It was found that endometrial transplants in the anterior chamber of the eye rhythmically bluish and blanch (Markee 1929). Kymographic records of these color changes were made in the following way: Six lines equal distances apart were drawn around the drum of a kymograph to represent the colors of 0, 10, 20, 30, 40, and 50 per cent of haemoglobin respectively. The color changes in the transplant were recorded by comparing the color of the transplant with the colors on a Tallqvist haemoglobinometer and turning the recording dial to the appropriate percentages. The fluctuations in the color of the transplants could thus be graphically recorded.

THE MODIFICATION INDUCED BY
FOLLICULAR HORMONE

When 20 rat units per kilogram of follicular hormone are injected into a rabbit the following modification of the uterine vascular rhythm occurs. Within 10 minutes the color of the transplant is noticeably intensified and within 15 minutes the transplant becomes 20 per cent redder. In 20 minutes a slight irregularity of the cycle develops and the ratio of the

time in vasoconstriction to that in vasodilation is greater than 1:6. Thirty minutes after the injection of follicular hormone the ratio is 1:10 or greater. These modifications in the vascular cycle continue until 40 minutes after the injection when the rhythmic vascular changes cease and the color of the transplant is comparable to that of 50 per cent haemoglobin.

The injection of follicular hormone that has been extracted from the urine of pregnant women also arrests the rhythmic vascular changes in vasodilation. The method of extracting the follicular hormone from the urine is only slightly different from the one described by Frank and Goldberger (1930) and consists of shaking 150 cubic centimeters of urine with 100 cubic centimeters of ether in a separatory funnel for 30 minutes drawing off the ether and repeating the extraction with a second sample of ether. The two samples of ether are combined and evaporated to dryness at room temperature under reduced pressure. The residue is dissolved in olive oil and injected subcutaneously. Since the extraction of the follicular hormone by this method requires only 1 hour and 10 minutes and the modification of the vascular rhythm occurs 40 minutes after the injection of the extract the test may be completed in 2 hours.

Since the rhythmic vascular changes in endometrial transplants onto the iris are arrested by the presence of large amounts of follicular hormone in the blood stream they are arrested either when follicular hormone is injected or when it enters the blood stream from the rabbit's own ovaries (Markee 1929). The vascular rhythm in the endometrial transplants onto the iris is therefore arrested in vasodilation 7 to 8½ hours after mating or the intravenous injection of urine from pregnant women. The modification of the vascular rhythm, which occurs at that time, is similar in respect to the modification that follows the injection of follicular hormone.

¹ Aided by a grant from the National Research Council Committee on Research in Problems of Sex.

THE DIRECT METHOD OF TESTING FOR PREGNANCY

The direct test has a number of advantages over the indirect one. Either gonadectomized or non-gonadectomized males or females may be used. The possibility exists that the non-ovariectomized rabbit may at times produce a sufficient amount of follicular hormone to cause a modification of the vascular rhythm in the endometrial transplants, but this is remote because the rabbit apparently does not ovulate spontaneously. Since a kymographic record is made of the uterine vascular changes immediately before the extract is injected, this possible source of error is eliminated. The main advantage of the direct over the indirect test is that the diagnosis can be made 40 minutes after the injection or 2 hours after the specimen of urine has been obtained. Only a limited number of animals are required since the same rabbit may safely be used every third day. A correct diagnosis of pregnancy by both the direct and indirect methods was made as early as the forty-seventh day after the beginning of the last menstrual flow.

Mazer (1930) states that although follicular hormone is not present in the blood in increased concentration during the first 8 weeks of pregnancy it is present in the urine during that period. He suggests that the reason for its elimination through the kidneys may be that it is injurious to the conceptus during the early stages of development. This hypothesis is supported by Kelley's (1931) finding that, in the guinea pig the injection of follicular hormone during the first 4 weeks of pregnancy causes abortion. Bland (1932) found that the Mazer test for pregnancy (based on an increase in the amount of follicular hormone in the urine) was as reliable as the Aschheim-Zondek test. Therefore, it would seem reasonable to suppose that a reliable diagnosis may be made as early in pregnancy by the direct method as by the Aschheim-Zondek method.

THE INDIRECT METHOD OF TESTING FOR PREGNANCY

Only non-ovariectomized females can be used in the indirect test. Since the intravenous injection of urine from pregnant women induces pseudo-pregnancy the animals should

not be used oftener than every third week. The diagnosis can not be made until 7 to 8½ hours after the injection of the urine. These unavoidable disadvantages in the use of the indirect test are compensated for by the fact that it is more easily made since untreated urine is injected. Since a record is made of the vascular changes in the endometrial transplants immediately before the urine is injected, it is definitely known whether or not the animal may safely be used. It is, of course possible that ovulation might be initiated by the handling of the animal at the time that the injection is made. However since no one who has used the Friedman test for pregnancy has reported such an occurrence this does not seem to be a serious or a probable source of error.

The Cohnheim method of transplantation into the eye (1877) is not a difficult one and the time spent preparing the animals is not important since the same animal is used repeatedly. A further saving of time is effected since it is not necessary to perform an exploratory operation either to determine whether the animal will be a reliable indicator or to make the diagnosis.

The greatest difficulty encountered in the use of these tests for pregnancy is inherent in both methods. As previously reported (Markee, 1932) the vascular changes observed in endometrial transplants in the anterior chamber of the eye are of two kinds: the rhythmic changes and those that follow fright. The former are arrested in vasodilation by follicular hormone but the latter are not. However follicular hormone causes a decrease in the intensity of the vasoconstrictions that follow fright. Hence the diagnosis is more reliably made, if the animal is observed under conditions that eliminate fright. To this end it is placed in a small box, three sides of which are tall enough so that it can not see over them. Since the presence of the observer seems to excite a rabbit especially if he stares into its eye, the best results are obtained by using a microscope that magnifies three times and has a focal length of about 20 inches.

In rabbits without an increased amount of follicular hormone, a vasoconstriction is induced only when the animals are frightened.

during the middle third of a vascular cycle. However, if the vascular cycles have been lengthened or arrested by the injection of follicular hormone, fright may induce a vasoconstriction in one of two transplants in one eye and not in the other.

Because of these facts, it is sometimes difficult to decide whether the vasoconstrictions observed are induced by fright or not. It has therefore been necessary to devise some method by which the observer may distinguish between the vasoconstrictions induced by fright and the spontaneous rhythmic vascular changes. The two kinds of vascular changes may easily be distinguished because a vasoconstriction occurs in the blood vessels of the ears 17 seconds after a rabbit is frightened. Hence vasoconstrictions that occur in the endometrial transplants at about the same time as the vasoconstrictions in the ear are fright vasoconstrictions and those that occur in the transplant alone are rhythmic vascular changes. During pregnancy tests the fright vasoconstrictions are ignored since they are not rhythmic vascular changes and are not completely inhibited by follicular hormone.

Specimens of urine from 147 pregnant and 26 non pregnant women were tested by both the direct and indirect methods and all of the diagnoses have agreed with the clinical histories. Veler and Doisy (1928) have shown that the amount of follicular hormone in the urine of pregnant women increases as pregnancy progresses. We have found that enough follicular hormone to effect the modification of the uterine vascular rhythm can be extracted from smaller amounts of urine as pregnancy progresses. However, since we have not used 24 hour samples, it has not been possible to compare our results with theirs nor to discover how small an amount of urine from a woman in the later months of pregnancy will evoke the reaction.

Both the direct and indirect tests for pregnancy are based on the modification of the vascular rhythm in endometrial transplants by the presence of relatively large amounts of follicular hormone in the blood stream of the test animals. The direct test is made by injecting the follicular hormone that has been extracted from 150 cubic centimeters of urine

That volume of urine has been used in all tests because it was not possible to extract enough follicular hormone from 150 cubic centimeters of urine from non pregnant women to arrest the rhythmic vascular changes in the endometrial transplants and because 150 cubic centimeters of urine from pregnant women yields enough follicular hormone to arrest the vascular rhythm.

In all probability, only part of the follicular hormone in the urine was extracted by the method that was used. However, the efficiency of the method of extraction determines only the amount of urine that is used, since if a high percentage of follicular hormone were obtained, less urine would be required to yield enough follicular hormone to arrest the rhythmic vascular changes in the endometrial transplants.

Although all the diagnoses made by the direct method have agreed with the clinical histories, it should be pointed out that if for any reason large amounts of follicular hormone should be present in the urine of non pregnant women, the rhythmic vascular changes would be arrested in vasodilation and so a false diagnosis of pregnancy would be made. This method is merely a test for the presence of increased amounts of follicular hormone in the urine and is only indirectly a test for pregnancy. It should also be pointed out that it is not definitely known just how soon after conception there is a marked increase in the amount of follicular hormone in the urine. Therefore, only experience will determine whether or not this method will reliably test for early pregnancy.

A considerable amount of time is spent extracting the follicular hormone from the urine since if it is not done by hand, the mixture of urine and ether will become foamy. This will sometimes happen no matter how carefully the extraction is made. For these reasons, the direct test may prove to be less satisfactory than the indirect one even though the diagnosis of pregnancy may be made 2 hours after the specimen has been obtained.

Although these two methods of arresting the rhythmic vascular changes in the endometrial transplants have so far been used only as tests for pregnancy, the direct method

might be used as a test for increased elimination of follicular hormone through the kidneys or for the presence of increased amounts of follicular hormone in the blood. The indirect method might be used as a test for increased amounts of hypophyseal hormone either in the urine or in the blood.

SUMMARY

1 The modification of the rhythmic vascular changes in endometrial transplants onto the ins that is induced by the injection of follicular hormone extracted from the urine from pregnant women, can be used as a test for pregnancy. The diagnosis of pregnancy can be made 2 hours after the specimen of urine has been obtained.

2 The intravenous injection of urine from pregnant women causes an increased production of follicular hormone and indirectly in-

duces a modification of the uterine vascular rhythm in the endometrial transplants. By means of this indirect test the diagnosis of pregnancy can be made 8½ hours after the urine has been injected

THE COMPARATIVE BACTERICIDAL ACTION OF MERCUROCHROME AND IODINE SOLUTIONS USED AS LOCAL TISSUE DISINFECTANTS¹JAMES STEVENS SIMMONS² WASHINGTON

Major M. C. U. S. Army

IT IS the purpose of this paper to present experimental data concerning the relative bactericidal value of such mercurochrome and iodine solutions as are commonly used locally for the purpose of sterilizing the unbroken skin, oral mucous membranes, abrasions and both superficial and deep wounds.

The present report deals with the continuation of a study of local tissue antiseptics which was begun several years ago at the request of the Medical Supply Division of the Office of The Surgeon General U. S. Army. One of the original aims of the investigation was to answer a hypothetical procurement question as to whether some locally produced tissue disinfectant might not be found suitable to replace tincture of iodine if for any reason it should become difficult for the Army to obtain iodine from the usual foreign sources. Mercurochrome 220 soluble was selected as one of the substances to be studied mainly because of its popular use as a general antiseptic and because of certain enthusiastic claims made concerning its supposed germicidal value.

In the earlier work with mercurochrome the author (10) determined its germicidal action on several representative species of pathogenic bacteria which might be encountered as contaminants on the unbroken skin while Rodriguez (6) studied its effect on the normal bacterial flora of the oral mucous membranes. The results of these two investigations which were published simultaneously in 1928 may be briefly summarized as follows. In the author's work three types of mercurochrome solutions were used (2 per cent aqueous, 2 per cent alcohol acetone aqueous and 5 per cent alcoholic) also two solutions of iodine (the U. S. P. tincture, 7 per cent and half strength tincture 3.5 per cent) for different time intervals on living skin contaminated with a variety of pathogenic organisms including *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus scarlatinae*, *Escherichia*

coli, *Clostridium welchii* and *Bacillus anthracis* respectively. Bactericidal action was estimated by preparing from each area of treated skin a series of carefully controlled cultures to determine whether the specific test organisms had been killed. From this work it was shown that while the mercurochrome solutions had some antibacterial action *in vitro* against the non-sporogenous organisms they were ineffectual even under these conditions against the spores of *Clostridium welchii* and that regardless of the type of organism its action was relatively weaker than that of tincture of iodine. The relative ineffectiveness of mercurochrome was emphasized still more strikingly by the results of the experiments in skin disinfection. In some instances the 5 per cent alcoholic solution of mercurochrome caused a reduction in the number of bacteria but in 45 of 46 tests it failed to sterilize the skin; the 2 per cent acetone alcohol aqueous solution also caused some numerical reduction of the organisms in certain tests but it too failed in 45 of 50 tests while the 2 per cent aqueous mercurochrome solution failed to sterilize the skin in 55 of 56 tests. Considering these results as a whole it is apparent that mercurochrome sterilized the skin in only 7 or 4.8 per cent of 145 tests and that it failed in 95.2 per cent. In contrast to these results the half strength tincture of iodine caused a reduction in viable organisms in 20 of 42 tests and sterilized the skin in the other 22 tests. The U. S. P. tincture of iodine failed only 7 times—in 2 tests with *Staphylococcus* and in 5 tests with *Clostridium welchii* spores—and in these 7 tests the numbers of viable organisms were reduced. Tincture of iodine was found to be effectively bactericidal in 51 or 87 per cent, of the 58 tests. These carefully controlled experiments which showed that the mercurochrome solutions used were relatively too ineffectual to be of practical value for the destruction of the 6 species of pathogenic bacteria present as con-

¹From the Department of Bacteriology, Army Medical School, Washington, D. C.²Assisted by George F. LaFollette, Staff Sergeant, Medical Department, U. S. Army.

taminants on living skin led to the conclusion that mercurochrome was not suitable for use as a substitute for tincture of iodine in pre-operative skin disinfection.

Unfavorable results were also obtained with mercurochrome by Rodriguez in his experimental investigation of this drug as a pre-operative disinfectant for use on the oral mucous membranes. His conclusions were as follows: Mercurochrome 250 soluble (2 per cent aqueous solution) is too feeble an antiseptic to be used safely as a surface disinfectant of the oral mucous membranes. The 5 per cent mercurochrome solution in alcohol and the mercurochrome-alcohol acetone preparations possess decided advantages over the aqueous solution, but fail in too large a proportion of cases to be considered effective in surface disinfection of the oral mucous membranes. Iodine in 3.5 per cent and even in 1.75 per cent strength, preferably in glycerin is an effective germicide from the standpoint of surface disinfection of the oral mucous membranes.

These observations have since been confirmed by other workers although there was some disagreement on the part of Reddish and Drake and later by Scott, Hill and Ellis (9). The former in an article which appeared simultaneously with those by Rodriguez and the author published experiments in which, by a different technique, mercurochrome and iodine were tested for disinfectant action on rabbit skin contaminated with a strain of *Staphylococcus aureus*. In this paper Reddish and Drake (5) claimed that a 2 per cent mercurochrome in aqueous-alcohol-acetone solution and tincture of iodine are equally effective in disinfecting the unbroken skin but it appears that their conclusions were not warranted by their published results, even with the one species of bacteria considered. Moreover these writers failed to support their broad conclusions by tests with the other important pathogenic skin contaminants. Also no mention was made of the fact that one of them (Reddish, 4) had previously stated in official individual reports from his laboratory in the Department of Agriculture, copies of which were furnished me, that, even *in vitro* mercurochrome was ineffective against such

spore forming bacteria as *Clostridium welchii* and *Clostridium tetani*. In one of these official reports made in 1925 Reddish stated that

Clostridium tetani is not killed by 5 per cent aqueous or 5 per cent alcoholic mercurochrome in 2 hours. Tincture of iodine kills it some time between 30 minutes and 1 hour but close to 30 minutes because it shows a \mp at 30 minutes. In another such report he showed that 5 per cent alcoholic mercurochrome failed to kill the Welch bacillus, *in vitro* in 2 hours, while *Clostridium welchii* is practically killed after 15 minutes exposure to tincture of iodine

and certainly entirely all killed by 30 minutes exposure. The following remark was added: "Tincture of iodine is decidedly better than 5 per cent alcoholic mercurochrome against *Clostridium welchii*, the commonest of the war wound anaerobes." The obvious discrepancies between these observations made by Reddish in 1925 and the conclusions published by Reddish and Drake in 1928 without any mention of *Clostridium welchii* or *Clostridium tetani* appear to detract considerably from the value of their statements on skin disinfection.

Delafield in reviewing these publications (5, 6, 10) commented as follows on the report by Reddish and Drake: Adopting a somewhat different technique to that used by J. S. Simmons (*supra*), conclusions are reached which are at variance with those of the latter investigator. Only one test organism was used—*Staphylococcus aureus* 209—and the bacteriological method was different. The 2 per cent alcohol acetone-aqueous solution of mercurochrome is said to be as effective as tincture of iodine, and, because of the well known objections to the latter to be far more suitable for skin disinfection. (The tabular statement of results does not appear to justify this sanguine view of the efficacy of mercurochrome.)

Sinclair in a report to The Surgeon General, U. S. Army dealing with his experimental studies of tissue disinfectants, made the following statement concerning mercurochrome:

In support of previous complete report by Major James S. Simmons and to controvert the editorial (2) criticism of his technique in the *Journal of the American Medical Association* September 8, 1928 a test was made, the

technique of Dr. G. I. Keddish being used. Methods and results are included in Protocol I enclosed. This experiment supports the previous report of Major Simmons that mercurochrome is not an effective substitute for iodine in skin disinfection. Although these results were obtained after strictly following the technique of Keddish (4) they are strangely diametrically opposite to results obtained by him. However they agree very closely with those obtained by Simmons from which he drew the following conclusion:

From the standpoint of bactericidal action tincture of iodine is far superior to any of the solutions used (mercurochrome) on unbroken skin for disinfection purposes.

In 1929 Scott Hill and Ellis (9) published an article in defense of the 2 per cent aqueous alcohol acetone solution of mercurochrome which had been presented as a pre-operative skin disinfectant in 1925 by Scott and Hill (8) who had made the claim that better skin sterilization is obtained with it than with iodine. While the more recent article dealt mainly with controversial matter it also included the results of disinfection tests with (a) unwashed human skin the bacterial contamination of which was necessarily variable as to quantity and species, and (b) with disinfection of shaven rabbit skin contaminated by applications of 24 hour broth cultures of *Staphylococcus aureus* 309. It will be noted that the latter method of preparing the skin contamination is essentially similar to that outlined in their original report in which they stated that the shaven rabbit skin was heavily inoculated by smearing it with 18 hour 1 per cent dextrose broth cultures. This point is emphasized only because of the marked disagreement between the results reported by Scott and Hill in 1925 and those by Scott Hill and Ellis in 1929. In the earlier article the tabular results indicated that within 2 $\frac{1}{2}$ or even 1 minute's time the 2 per cent mercurochrome solution caused complete sterilization of skin contaminated with such heavy inoculations of *Staphylococcus aureus* in all of 25 tests. However according to the 1929 report the same type of mercurochrome solution applied for 5 or more minutes to rabbit skin similarly contaminated with 24 hour broth cultures of

Staphylococcus failed to sterilize the skin and the cultures showed heavy growth of *Staphylococcus aureus* in 100 per cent of the 15 tests.

In 9 parallel skin tests with tincture of iodine the cultures also showed heavy growth and 7 were recorded as sterile. In the later article the authors concluded that the two drugs were equally effective in sterilizing the uncleaned human skin but no explanation was offered for the modification of their earlier claim concerning the supposed superiority of mercurochrome or for the discrepancies in their various published results. These claims by Scott Hill and Ellis which agree in substance with those of Keddish and Drake are subject to similar objections and obviously cannot be accepted on the experimental evidence offered.

In 1931 Scott and Birkhaug (7) reported the results of an investigation made to determine the relative bactericidal value of certain skin disinfectants including (a) metaphen (0.5 per cent in alcohol acetone solution) (b) tincture of iodine (7 per cent) and (c) mercurochrome (2 per cent in alcohol acetone solution). Each solution was used in 104 three minute tests including both surface and deep disinfection tests on unwashed human skin and in 125 three minute tests with rabbit skin contaminated with undiluted 18 hour broth cultures of *Staphylococcus aureus*, *Streptococcus hemolyticus*, *Bacillus coli* and *Bacillus subtilis* (spores) respectively. The results were determined by a technique somewhat similar to that used in my investigations mentioned above. After 3 minutes treatment of the skin cultures were made with two moistened cotton swabs which were first rubbed vigorously against the center of the treated area and then immersed in 100 cubic centimeters of Douglas broth contained in a 250 cubic centimeter Frlenmeyer flask. After incubation for 48 hours at 37 degrees C the results of skin sterilization were determined according to the growth of bacteria in the test cultures. Their results were as follows. In the surface tests with rabbit skin heavily contaminated with undiluted 18 hour broth cultures of *Staphylococcus aureus*, *Streptococcus hemolyticus*, *Bacillus coli* and the spore bearing *Bacillus subtilis* metaphen killed the organisms in 89.7 per cent tincture of iodine

Fig. From Report to The Surgeon General, U. S. Army by Major Charles G. Sinclair, M. C. Department of

Bacteriology Army Medical School, Washington, D. C. September 1928.

in 70.7 per cent and mercurochrome in 51.5 per cent of the tests. The results in the deep sterilization tests on rabbit skin contaminated with the same species of bacteria were as follows: metaphen 87 per cent, tincture of iodine 47 per cent, and mercurochrome 26 per cent. In the disinfection tests on the surface of normal human skin, metaphen was effective in 98 per cent, tincture of iodine 96.1 per cent, and mercurochrome in 28.8 per cent of 52 tests each. In the deep tests on human skin epithelial scrapings being used, metaphen produced sterility in 94.2 per cent, tincture of iodine in 84.6 per cent, and mercurochrome in 3.8 per cent of 52 tests each. Although no experiments were reported with *Clostridium welchii* or *Clostridium tetani*, this investigation by Scott and Birkhaug again confirms the earlier conclusions of Simmons, Sinclair and others, concerning the relative ineffectiveness of mercurochrome as a skin disinfectant.

More recently Kelsor and Mohr have reported the results of experiments from which

they concluded that the commonly marketed 2 per cent solution of mercurochrome 220 soluble is not a satisfactory skin disinfectant for use in veterinary practice. Compared with tincture of iodine (U.S.P.) for such purpose, the latter proved superior. A concentration of 1 part of tincture of iodine (U.S.P.) in 10 parts of a suspension of tetanus spores killed the spores within 10 minutes. A similar concentration of mercurochrome (2 per cent aqueous) failed in this respect. Mercurochrome is decidedly ineffective as a germicide in the presence of blood serum, tissue exudates and possibly other protein substances. Such substances interfered much less with the bactericidal action of tincture of iodine.

Thus the available experimental data indicates that while mercurochrome possesses some antiseptic action against certain organisms *in vitro*, its obvious limitations are such that it need not be considered further as a substitute for iodine in disinfection of the mucous membranes or skin.

Fig. 2. Infu-lon agar and 10-1 agar plate cultures from superficial incised wound contaminated with *Staphylococcus aureus* and treated with 2 per cent mercurochrome and tincture of iodine, respectively. After inoculation of medium with material from this wound, a pure culture of *Staphylococcus aureus* was streaked across the Infu-lon agar plates; the control on bacteria in 10-1 represented by the confluent linear growth.

PRESSENT INVESTIGATION—EXPERIMENTAL

The results of previous experiments showing mercurochrome to be of relatively little value for pre-operative skin disinfection suggested that the drug might be even less effective in the presence of such proteins as are to be encountered in wounds. However because of certain unsubstantiated claims concerning the supposed effectiveness of mercurochrome under these conditions, the investigation was continued to include this phase of the subject.

Materials and methods. Several different solutions of both mercurochrome and iodine were tested as wound disinfectants, but a large proportion of the experiments were done with a commercially prepared solution labeled

Mercurochrome 2 per cent solution dibromoxymercuri fluorescein general antiseptic in place of iodine. Tincture of iodine was used in parallel control tests. These two solutions were selected purposely because both are commonly used as local applications on abrasions and superficial wounds. The bacteria considered in this report are *Staphylococcus aureus* and *Streptococcus pyogenes*. Because of the consistent resistance of these organisms to mercurochrome, the original plan to include species of spore-forming bacteria was considered unnecessary. As in the experiments on skin disinfection, broth cultures or saline suspensions of the test organisms

were used to contaminate uniformly (a) cutaneous abrasions, (b) superficial incised wounds, and (c) deep incised wounds made through the shaven abdominal skin of rabbits. The animals were immobilized on boards throughout the experiments. Sterile towels were used to protect the wounds in the tests requiring long exposure and the necessary precautions against accidental contamination were observed. Within 5 minutes after adding the bacteria, the antiseptic solutions were applied to the contaminated wounds and to the adjacent skin for the desired periods of time varying from 5 minutes to 3 hours. Cultures were then made to detect the survival of any viable test organisms by collecting materials from each wound on moist sterile cotton swabs which were immediately rubbed over the surfaces of blood agar, serum agar or nutrient agar plates, and then used to inoculate flasks containing 100 cubic centimeters or more of beef infusion broth pH 7.4 to 7.6. In each experiment parallel cultures were made in a similar manner from untreated wounds to furnish a comparison with results obtained in the tests, and as usual, adequate controls were made to eliminate the possibility of confusion due to bacteriostasis in the test cultures. In a large number of experiments conducted under a variety of conditions the following results were obtained:

1. *Disinfection of contaminated abrasions of the skin.* As indicated in Table I, a total of 42 skin abrasions, 30 contaminated with *Staphy-*

TABLE I—DISINFECTION OF ABRASIONS OF RABBIT SKIN

	Duration of wound treatment (minutes)	Number of wounds treated with each drug	Number sterile after treatment with	
			per cent aqueous Mercuriochrome	Tincture of iodine

lococcus aureus and 12 with *Streptococcus pyogenes*, were treated with mercurochrome. Cultures made from these treated lesions after 5, 30 and 120 minutes showed growth of the test organisms as follows: In one test with *Staphylococcus aureus* there was one colony in 2 there were 30 colonies while in the remaining 39 tests the growth was as luxuriant as in cultures from the untreated control abrasions. In the parallel series of 42 abrasions treated with tincture of iodine 8 showed growth of the test organisms in cultures as follows: four showed about one fourth as much growth as the controls, two had 25 colonies each, one had 23 colonies and one had 3 colonies. All cultures from the remaining 34 abrasions were sterile. Thus it is apparent that while mercurochrome caused very little reduction in the numbers of contaminating organisms and failed to sterilize any of the wounds, tincture of iodine resulted in sterilization in 80.9 per cent of the abrasions and in the remaining 8 caused a numerical reduction in the test organisms.

II *Disinfection of contaminated superficial incised wounds*. The results obtained in bactericidal tests with superficial incised wounds are indicated in Table II. The 2 per cent aqueous solution of mercurochrome used on 89 such wounds contaminated with *Staphylococcus aureus* caused some numerical reduction of the organisms in 58 instances. In 23 of these tests the growth was about half as luxuriant as on control plates; in 10 it was esti-

mated at one-fourth while in 2 tests there were 5 and 10 colonies respectively. Cultures from the remaining 31 wounds showed luxuriant growths similar to those obtained from untreated control wounds. This solution of mercurochrome used on 14 wounds contaminated with *Streptococcus pyogenes* failed to cause any appreciable decrease in the numbers of test organisms. Slightly better results followed the use of 2 per cent mercurochrome solution in water, alcohol and acetone on 21 wounds contaminated with *Streptococcus pyogenes*. In 8 of the tests there was some reduction in growth; 3 were reduced about one half, one to about one-fourth while 4 others showed 1, 2, 7 and 50 colonies respectively. In the 13 remaining tests, the bacterial growths were luxuriant, resembling in amount the cultures from untreated wounds. Considering the results with mercurochrome as a whole, this drug was used on a total of 124 contaminated wounds, none of which was sterilized. Tincture of iodine used similarly on 124 wounds gave the following results:

Cultures from 89 wounds contaminated with staphylococci showed that 64 were sterile while those from the remaining 15 showed a reduction in living organisms. In one there were 80 colonies in 3 less than 50 in 4 less than 25 and in 7 less than 10 colonies each. Cultures from the 35 wounds contaminated with streptococci gave essentially similar results. Seven showed reduced growths 1 had 80 colonies 3 less than 50 and 3 less than 10 colonies each while all cultures from the remaining 28 wounds were sterile.

To recapitulate mercurochrome failed to sterilize any of the 124 superficial incised wounds in which it was used while tincture of iodine was effective in 103 or 83 per cent.

III *Disinfection of contaminated deep incised wounds.* The 2 per cent aqueous solution of mercurochrome was used on 32 deep incised wounds contaminated with *Staphylococcus aureus* and on 12 contaminated with *Streptococcus pyogenes* with the results shown in Table III. Cultures from these 44 treated wounds showed luxuriant growths of the test organisms and there was no apparent numerical reduction except in 3 tests recorded as +++ and + respectively. After treatment with tincture of iodine cultures from 7 wounds showed a reduction of one half (++) 11 tests showed a reduction of one fourth (+) in 1 test there were 80 colonies in 2 there were 30 colonies each and in 4 there were 10 colonies or less. Cultures from the remaining 19 or 43.1 per cent of the wounds were sterile.

TABLE III—DISINFECTION OF DEEP INCISIONS OF RABBIT SKIN

SUMMARY

1 Three types of wounds—skin abrasions superficial incisions and deep incisions—contaminated with undiluted broth cultures of either *Staphylococcus aureus* or *Streptococcus pyogenes* were treated for various periods of time with solutions of iodine and mercurochrome respectively.

2 Application of tincture of iodine to 151 wounds contaminated with staphylococci resulted in sterile cultures as follows: abrasions 83.4 per cent superficial incisions 83.1 per cent and deep incisions 31.2 per cent while its use on 59 wounds contaminated with streptococci resulted in sterilization as follows: abrasions 75 per cent superficial incisions 80.9 per cent and deep incisions 8 per cent. In brief of 210 contaminated wounds treated with tincture of iodine the cultures from 156 or 74.2 per cent were sterile.

3 Mercurochrome used under similar conditions caused relatively little reduction in the numbers of viable test organisms and failed to sterilize any of the 210 wounds.

CONCLUSION

The 2 per cent aqueous solution of mercurochrome advocated for the first aid treatment of wounds is a relatively weak antiseptic. When used experimentally for the destruction of *Staphylococcus aureus* or *Streptococcus pyogenes* in abrasions or incised wounds it was decidedly less bactericidal than tincture of iodine. Mercurochrome is comparatively so ineffective in the sterilization of contaminated living tissues that it should not be considered as a substitute for iodine.

EXCRETION UROGRAPHY BY MEANS OF THE INTRAVENOUS AND ORAL ADMINISTRATION OF SODIUM ORTHO-iodoHIPPURATE WITH SOME PHYSIOLOGICAL CONSIDERATIONS¹

PRELIMINARY REPORT

M SWICK, M D New York

ALTHOUGH the original contribution to excretion urography with the use of iopax (uroselectan) as described by the author (11) has proved useful in the clinical investigation of the urinary tract (7) certain desirable features have been wanting. The present paper deals with another substance² newly developed for excretion urography and is based upon the physiological principle of detoxification and on other metabolic considerations. The fundamental concept of this work is the utilization of an organic nucleus representing a normal product of animal metabolism, as a carrier for the radiopaque element necessary for the x-ray visualization of the urinary tract. The compound now proposed is sodium ortho-iodohippurate a halogen derivative of a substance normally found in the human urine.

In the consideration of a new substance to be used for excretion urography the following were the guiding principles:

- a. That the substance be highly soluble and approximate the hydrogen ion concentration of the blood.
- b. That the radiopaque halogen be bound in a stable form to an organic nucleus.
- c. That the nucleus be one which is produced in the course of animal metabolism.
- d. That it be highly water soluble. A high degree of water solubility is generally paralleled by a greater tendency for rapid absorption and excretion and also permits the intravenous administration in small volume. Moreover a substance that is readily and rapidly excreted from the body is less apt to produce toxic manifestations. In this connection it is also important to note that organically bound iodine for excretion urography has been found to be well tolerated by the human

body and not associated with the picture of iodism.

e. That the substance be a sodium salt, since the sodium ion is most suitable from a physiological standpoint.

f. That the substance be selectively and rapidly excreted by the kidney in high concentration.

g. That it be well tolerated.

h. That it be comparatively inexpensive.

Of the metabolic studies already reported concerning benzoic and hippuric acids the following points appeared noteworthy and promising in the development and rationale of the present investigations:

a. The introduction of benzoic acid or its sodium salt into the animal organism results in its conjugation with glycine and in the excretion of hippuric acid or its sodium salt in the urine. In similar fashion it has been shown that the administration of iodobenzoic acid in the dog and rabbit results in the urinary excretion of iodohippuric acid (Novello, Miriam, and Sherwin).

b. The synthesis and elimination of hippuric acid after benzoic acid administration represent processes of detoxification (Caonka, Griffith and Lewis, Raiziss and Dubin, Lewinski, Dakin and Lewis).

c. Sodium hippurate is a very suitable organic parent-substance for combination with iodine or bromine since (1) it is extremely soluble in water (2) is neutral in solution (Corbeld and Melhuish) (3) represents a product of metabolism (4) is well tolerated and (5) is quantitatively excreted (95 per cent) in 6 hours after the intravenous administration to the rabbit (Raiziss, Raiziss and Ringer, Griffith and Lewis, Caonka, Lewis).

With these observations and considerations in mind and after consultation with Dr. Sobotka to whom thanks are expressed for his

¹This new medium for excretion urography is as yet not procurable for general use.

²From the Second Surgical Service, the Radiologic and Laboratory Divisions, the Mount Sinai Hospital, New York. Work carried out with the aid of grants from The Edmund Lehman Fellowship Fund.

Fig. 1 Intravenous urogram man, 38 years old. Normal primary tracts. 30 grams of substance administered.

Fig. 2 Oral urogram man, 32 years old. Dilatation of both kidney pelves. Kinking of right ureter. Underlying condition—urethral stricture. Fifteen grams of substance administered.

kind co-operation the author carried out a series of experiments resulting finally in the demonstration that sodium ortho-iodohippurate possesses the necessary qualifications.

In accordance with the present investigations this substance proves to be a non toxic highly soluble neutral and radiopaque salt which is selectively excreted through the urinary tract in sufficiently high concentration to yield satisfactory urograms.

Sodium ortho-iodohippurate (38.8 per cent iodine) is easily soluble in less than its own weight of water and can be prepared and distributed in sterile solution ready for use. The solution remains unchanged in color or reac-

tion after sterilization or on standing. The iodine exists in a stable organically bound state. Iodism has never been observed. The tolerance for this compound is good. Rabbits usually tolerate 2 to 2.5 grams of substance per kilogram of body weight administered intravenously in 30 per cent concentration over a period of about 10 minutes. Patients suffering from tuberculosis or Graves' disease have not shown reactions after injection. Manifestations of injury to the kidney as demonstrated by urine analysis in the human as well as tissue examination in the rabbit have not been observed. Microscopic examination of the liver, lung and heart similarly fails to reveal evidences of injury. The tissues selected for examination have been obtained from rabbits killed 24 hours to 4 months after injection. The substance is excreted as such through the urinary tract and may be recovered as the insoluble acid on the addition of a dilute mineral acid. On recrystallization from hot water with the aid of charcoal the recovered sub-

TABLE I

stance appears white and crystalline. Identification of this substance has been accomplished by means of melting point nitrogen and iodine determinations. The urines from patients injected with sodium ortho-iodohippurate have never shown positive Fehling or Benedict reactions, indicating that the formation of iodo-benzoic acid and its subsequent excretion and conjugation with glycuronic acid is unlikely. Furthermore the quantitative determinations of the recovered substance would speak against the presence of either excreted free iodobenzoic acid or iodobenzoyl glycuronic acid.

Normally from 90 to 95 per cent of the substance can be recovered from the urine within 8 hours after the injection (based upon iodine determinations). Between 70 and 80 per cent (in terms of iodine) is recovered during the first 2 hours and between 60 and 66 per cent is excreted in the first hour. Table I illustrates the curves of excretion in normally functioning kidneys obtained after the administration of 10, 15 and 20 gram doses respectively. From these results it is evident that the normally functioning kidney excretes this substance in a high concentration and within a short period.

It is evident that a certain concentration of the radiopaque element the iodine is necessary for roentgenological visualization.

This concentration depends upon renal and extrarenal factors influencing renal excretion as well as upon the dose administered. Broadly speaking good visualization poor or no visualization is dependent upon the above enumerated factors. Other considerations bearing upon the relationship between renal function and roentgenological visualization are discussed in other publications.

Therefore as in the case of other substances developed for excretion urography so with sodium ortho-iodohippurate it is essential to bear in mind the factors governing renal excretion when evaluating this method and the results obtained with it.

Procedure and reactions. Satisfactory urograms have been obtained in adults with doses varying between 10 and 15 grams of substance dissolved in distilled water in 40 per cent concentration. The injection is carried out over a period of 5 minutes. The first film is taken 10 minutes after the injection, two subsequent exposures being made at 20 minute intervals. Whenever functional disturbances are present additional films should be taken to determine definitely the absence of visualization or the presence of late visualization. Aside from a slight sensation of generalized warmth there have been no reactions. Thrombosis at the site of injection has not been observed. To date 125 cases have been injected 20 and 30

grams of substance having been administered to some cases, with the larger dose occasionally transient vomiting occurs. Children under 13 years of age have received 10 gram doses without ill effects. A one year old child in whom suitable roentgenograms were observed, showed no reactions from a 10 gram dose. In a 3 year old child receiving 6 grams of substance satisfactory roentgenograms were also obtained.

Oral administration in the human has given encouraging results. Of 14 cases 50 per cent yielded satisfactory urograms. The dose administered by mouth has been between 10 and 15 grams dissolved in simple syrup. No reactions have been noted. Diagnostic pictures have been obtained 90 and 135 minutes after administration. It appears that the results by the oral route will not be as consistently good as by the intravenous one. Further investigations with the oral administration are in progress in the hope of improving the results.

Of great aid in obtaining clearly defined and readable urograms is the application of a moderate degree of compression by means of an air inflated balloon over the region of the urinary bladder. A more detailed consideration of this aspect is dealt with in other publications.

Field of application and contra indications
In order to avoid repetition the reader is referred to the literature dealing with excretion urography wherein these phases are discussed.

Additional investigations with related substances such as the sodium salts of meta and para iodohippuric acids diiodohippuric acid and of bromiodohippuric acid iodobenzoyl urea, and finally the administration of moniodo- and diiodobenzoates of sodium in con-

junction with glycine by the intravenous and oral routes are being continued.

SUMMARY

The author presents sodium ortho-iodohippurate for excretion urography. It is felt that this substance has the following advantages:

- 1 It is relatively inexpensive
- 2 It is without toxic effects
- 3 It can be administered in a small volume of diluent
- 4 A relatively small quantity of the salt is required for satisfactory urograms
- 5 It yields satisfactory roentgenograms
- 6 Satisfactory results have been obtained by the oral route

The author wishes to express his gratitude to Mr. Albert P. Sachs and the Zonite Products Corporation for their valuable assistance to Drs. Beer, Gross, Jaehs, and Edman for their kind co-operation.

THE USE OF ANTICOLIBACILLARY SERUM IN SURGERY¹

PROFESSOR HYACINTHE VINCENT, PARIS, FRANCE

Professor in the Collège de France, Laboratory of Infectious and Epidemic Diseases, Member of the Academy of Medicine, Paris; Lieutenant General, Sanitary Service, French Army

I HAVE shown that certain strains of *Bacillus coli* possess both experimentally and in human infection, a considerable virulence and toxicity which in man may be manifested by medical and surgical conditions of great gravity. I have also shown that *Bacillus coli* (the atypical as well as the normal strains) has the power of secreting two toxins, one a neurotropic thermolabile exotoxin, the other an enterotropic and hepatotropic thermolabile endotoxin. The association of these two toxins produces a pathological state that determines the widely varying phenomena which accompany colibacillary septicemias as well as acute or chronic local colibacillary infections. Such a pathological state explains the nervous troubles observed in chronic enteropathies (particularly mucomembranous enteritis) paralyses etc. which are brought about by the exotoxin. The endotoxin affects particularly the glands of Lieberkuehn, the biliary secretion, and the hepatic parenchyma. It produces severe symptoms, such as diarrhoeal crises. The toxic infection may even terminate in icterus gravis or acute yellow atrophy of the liver (H. Vincent).²

My clinical and experimental researches have led me to the preparation of an antitoxic and anti-infectious anticolibacillary serum. This serum injected into patients suffering from very grave medical conditions *Bacillus coli* septicemia, cholecystitis of the same origin, suppurative pyelonephritis (in adults of all ages, pregnant women, children), chronic enterocolitis, paralyses of colibacillary origin etc. brings about a rapid recovery such as I have already reported.³

Moreover *Bacillus coli* commonly brings about maladies which interest the surgeon in particular. It has therefore, seemed worth

while to point out the effect that this new anticolibacillary serum may produce in affections of a surgical nature.

Few organs escape infections due to the colon bacillus, but in general the abdominal viscera are the ones most frequently affected by this micro-organism because it lives normally in their vicinity i.e. the intestine. The peritoneum on account of traumatism of the intestine (contusion, wounds by penetrating instruments, gunshot wounds, etc.) is frequently invaded by micro-organisms of the digestive tract. One of the most common as well as the most dangerous, is certainly *Bacillus coli*. Perforative or gangrenous appendicitis constitutes equally one of the most important indications for anticolibacillary serotherapy. Pyosalpingitis is the expression of very diverse infections among which those by *Bacillus coli* are very common. The same is true of pelvic abscesses. In all of these affections it is advantageous before injecting the serum, to make a microbiological examination.

Primary suppurative pyelonephritis of *Bacillus coli* origin requires as early application as possible of serotherapy. This malady as I shall show is rapidly cured by this method. In pregnancy and in the puerperium, when the bacillus has invaded the blood and has lodged, as a result, in the renovesical apparatus, the infectious symptoms disappear within a few days. I shall review the principal surgical maladies in which serotherapy serves as a particularly efficacious aid to the surgeon and operator.

Statistics of mortality from gangrenous appendicitis with perforation and late operation indicate a death rate of 7 cases out of 10 (Cook, of Nancy, Vielle of Bordeaux) 3 cases out of 6 (Dr. Folsy) 70 per cent (Racovatz) etc.

Gangrenous appendicitis constitutes one of the most important indications for sero-

2261, 2262, 2263, 2264, 2265, 2266, 2267, 2268, 2269, 2270, 2271, 2272, 2273, 2274, 2275, 2276, 2277, 2278, 2279, 2280, 2281, 2282, 2283, 2284, 2285, 2286, 2287, 2288, 2289, 2290, 2291, 2292, 2293, 2294, 2295, 2296, 2297, 2298, 2299, 2300, 2301, 2302, 2303, 2304, 2305, 2306, 2307, 2308, 2309, 2310, 2311, 2312, 2313, 2314, 2315, 2316, 2317, 2318, 2319, 2320, 2321, 2322, 2323, 2324, 2325, 2326, 2327, 2328, 2329, 2330, 2331, 2332, 2333, 2334, 2335, 2336, 2337, 2338, 2339, 2340, 2341, 2342, 2343, 2344, 2345, 2346, 2347, 2348, 2349, 2350, 2351, 2352, 2353, 2354, 2355, 2356, 2357, 2358, 2359, 2360, 2361, 2362, 2363, 2364, 2365, 2366, 2367, 2368, 2369, 2370, 2371, 2372, 2373, 2374, 2375, 2376, 2377, 2378, 2379, 2380, 2381, 2382, 2383, 2384, 2385, 2386, 2387, 2388, 2389, 2390, 2391, 2392, 2393, 2394, 2395, 2396, 2397, 2398, 2399, 2400, 2401, 2402, 2403, 2404, 2405, 2406, 2407, 2408, 2409, 2410, 2411, 2412, 2413, 2414, 2415, 2416, 2417, 2418, 2419, 2420, 2421, 2422, 2423, 2424, 2425, 2426, 2427, 2428, 2429, 2430, 2431, 2432, 2433, 2434, 2435, 2436, 2437, 2438, 2439, 2440, 2441, 2442, 2443, 2444, 2445, 2446, 2447, 2448, 2449, 2450, 2451, 2452, 2453, 2454, 2455, 2456, 2457, 2458, 2459, 2460, 2461, 2462, 2463, 2464, 2465, 2466, 2467, 2468, 2469, 2470, 2471, 2472, 2473, 2474, 2475, 2476, 2477, 2478, 2479, 2480, 2481, 2482, 2483, 2484, 2485, 2486, 2487, 2488, 2489, 2490, 2491, 2492, 2493, 2494, 2495, 2496, 2497, 2498, 2499, 2500, 2501, 2502, 2503, 2504, 2505, 2506, 2507, 2508, 2509, 2510, 2511, 2512, 2513, 2514, 2515, 2516, 2517, 2518, 2519, 2520, 2521, 2522, 2523, 2524, 2525, 2526, 2527, 2528, 2529, 2530, 2531, 2532, 2533, 2534, 2535, 2536, 2537, 2538, 2539, 2540, 2541, 2542, 2543, 2544, 2545, 2546, 2547, 2548, 2549, 2550, 2551, 2552, 2553, 2554, 2555, 2556, 2557, 2558, 2559, 2560, 2561, 2562, 2563, 2564, 2565, 2566, 2567, 2568, 2569, 2570, 2571, 2572, 2573, 2574, 2575, 2576, 2577, 2578, 2579, 2580, 2581, 2582, 2583, 2584, 2585, 2586, 2587, 2588, 2589, 2590, 2591, 2592, 2593, 2594, 2595, 2596, 2597, 2598, 2599, 2600, 2601, 2602, 2603, 2604, 2605, 2606, 2607, 2608, 2609, 2610, 2611, 2612, 2613, 2614, 2615, 2616, 2617, 2618, 2619, 2620, 2621, 2622, 2623, 2624, 2625, 2626, 2627, 2628, 2629, 2630, 2631, 2632, 2633, 2634, 2635, 2636, 2637, 2638, 2639, 2640, 2641, 2642, 2643, 2644, 2645, 2646, 2647, 2648, 2649, 2650, 2651, 2652, 2653, 2654, 2655, 2656, 2657, 2658, 2659, 2660, 2661, 2662, 2663, 2664, 2665, 2666, 2667, 2668, 2669, 2670, 2671, 2672, 2673, 2674, 2675, 2676, 2677, 2678, 2679, 2680, 2681, 2682, 2683, 2684, 2685, 2686, 2687, 2688, 2689, 2690, 2691, 2692, 2693, 2694, 2695, 2696, 2697, 2698, 2699, 2700, 2701, 2702, 2703, 2704, 2705, 2706, 2707, 2708, 2709, 2710, 2711, 2712, 2713, 2714, 2715, 2716, 2717, 2718, 2719, 2720, 2721, 2722, 2723, 2724, 2725, 2726, 2727, 2728, 2729, 2730, 2731, 2732, 2733, 2734, 2735, 2736, 2737, 2738, 2739, 2740, 2741, 2742, 2743, 2744, 2745, 2746, 2747, 2748, 2749, 2750, 2751, 2752, 2753, 2754, 2755, 2756, 2757, 2758, 2759, 2760, 2761, 2762, 2763, 2764, 2765, 2766, 2767, 2768, 2769, 2770, 2771, 2772, 2773, 2774, 2775, 2776, 2777, 2778, 2779, 2780, 2781, 2782, 2783, 2784, 2785, 2786, 2787, 2788, 2789, 2790, 2791, 2792, 2793, 2794, 2795, 2796, 2797, 2798, 2799, 2800, 2801, 2802, 2803, 2804, 2805, 2806, 2807, 2808, 2809, 2810, 2811, 2812, 2813, 2814, 2815, 2816, 2817, 2818, 2819, 2820, 2821, 2822, 2823, 2824, 2825, 2826, 2827, 2828, 2829, 2830, 2831, 2832, 2833, 2834, 2835, 2836, 2837, 2

therapy.¹ This serum is in fact, a precious adjuvant to surgical intervention. *Bacillus coli* is the agent almost constant in peritonitis so often fatal and in septicemias of appendicular origin. This bacillus exists on the surface of the appendix and in the pus in prodigious quantities. I have recovered it sixteen times in seventeen cases of gangrenous appendicitis from the cloudy or purulent fluid surrounding the necrotic appendix. The anaerobes *Bacillus perfringens*, *Bacillus fragilis*, *Bacillus funduliformis*, *Bacillus fusiformis* etc. are much more rarely present (about one in four), and in small numbers. Nevertheless before operating in such cases I advise the administration of multivalent antigangrenous serum² or anticolibacillary serum the one or other introduced into the operative field and injected simultaneously under the skin.

This is the technique systematically employed in various surgical services notably at the Val-de-Grâce (Professors Duguet, Clavelin, Paltre, Lacaze and others) by Dr Foisy of Chateaudun by Dr Guibal of Baziers by Professor Forgey of Montpellier by Professor Laffitte of Niort and other surgeons. This treatment brings about 'ideally simple' recovery (Clavelin). It prevents the too frequent dangers which accompany gangrenous appendicitis with perforation and peritonitis in operations of necessity (Dr Foisy surgeon in chief of the hospital of Chateaudun).

I shall give two examples from among many others.

Louis S. aged 27 years admitted to the Val-de-Grâce, December 3 1928. In the service of Professor Paltre. The onset was 48 hours previously but the symptoms had become markedly worse 10 hours before arrival at hospital and consisted of greenish vomiting hiccough ballooning of the abdomen and generalized contraction of the walls. There had been passage of gas for 10 hours. Intestinal obstruction and general condition were grave. Temperature 103.1 degrees pulse 140 and hardly perceptible. The operation by Dr Lacaze showed the appendix gangrenous in the terminal two-thirds, and ruptured into the peritoneal cavity without any walling off. Small stercoral calculi were found in the free perito-

neum and abundant cloudy foul-smelling fluid in all the peritoneal folds and the pouch of Douglas. The intestinal loops were dilated red and like ground glass in appearance. After operation 60 cubic centimeters of anticolibacillary serum and 20 cubic centimeters of multivalent antigangrenous serum were injected subcutaneously the dose being repeated on the following day. The treatment was continued in diminishing doses and the temperature returned to normal on the fourth day. Six days after operation the drains were removed. Aside from the serum reaction recovery was uneventful.

In this serious case of gangrenous appendicitis with widely diffused peritonitis there followed extremely simple and rapid recovery under the treatment.

In the following case reported to me by Dr Machavoine former interne Hôpitalux de Paris there is another remarkable example. It may be summed up thus:

Treatment of generalized peritonitis after perforation of appendix by Vincent's anticolibacillary serum and hypertonic salt solution. Recovery.

The patient was a young woman of 25 years stricken November 7 1928 with gangrenous appendicitis with perforation of the appendix followed by acute peritonitis. Operation 48 hours afterward was difficult and prolonged (14 hours). The patient was transported in emergency to the clinic by automobile over a rough road 60 kilometers long. The surgical intervention was of necessity done under the most unfavorable conditions. There was present a quantity of foul liquid which flowed out in all directions. The entire appendix was gangrenous and perforated. On the following day November 10 the patient was in a state of profound shock and in extremely grave condition. There were ballooning of the intestines hiccough vomiting fecal retention etc. Pulse was about 110. The usual treatment (glucose solution cardiac tonics etc.) was given but without much hope according to the surgeon 'because the patient seemed lost.'

On November 11 there was administered the first injection of 60 cubic centimeters of anticolibacillary serum which had been procured in all haste from Paris. The injections were continued 40 cubic centimeters being given every 4 hours on November 12 13 and 14. At this time the danger seemed to be over and it was not considered necessary to continue the anticolibacillary serotherapy. As the patient showed signs of intestinal obstruction there were given on November 12 and the two days following intravenous injections of hypertonic salt solution by Grosset's method. 'The situation which had seemed desperate and which was becoming worse, was miraculously transformed (Dr Machavoine). Finally the patient left the surgical clinic on December 2 entirely cured of the serious symptoms which had seemed to point to certain death.'

² H. Vincent and G. Boudet, Compt. rend. Acad. d. Sc., 1928, 18, 487, 127-142, 205-206, 219, 487, 183.

Dr Foucault of Poitiers also published a series of observations of appendicitis with perforation and with beginning peritonitis or even with generalized peritonitis which were cured by surgical intervention aided by serotherapy. One of the most remarkable cases was that of a little girl, aged 8 years.

The surgeon saw her for the first time "in a state of diffused peritonitis of appendicular origin," with the abdomen ballooned out, fecal vomiting, pulse 158 and temperature 99 degrees. The case was 48 hours old, and the mother had purged the child the day before. When the abdomen was opened, the peritoneal cavity was found to be full of pus, as were the right iliac fossa, pouch of Douglas, and left iliac fossa. The general condition was very grave. Operation was done under novocain. At the same time anticolibacillary serum was injected. After 24 hours the pulse had dropped to 110 and the general condition so desperate the day before, showed great amelioration. After 48 hours the improvement was even more noteworthy. The pulse was 80. The child recovered. She had, however, been considered as lost, and intervention had been done in extremis.

Dr Laffitte of Nîort has reported similar cases to me.

In cases of generalized peritonitis of appendicular origin in which prognosis is fatal, one cannot advise too strongly the injection very early of large doses of serum. 60, 80 or 100 cubic centimeters in adults, 40 cubic centimeters in children, renewing the injections as often as necessary and diminishing the dosage when the general and local conditions are both improving.

These facts demonstrate what great security such serotherapy brings to the surgeon and that one may employ this method in gangrenous appendicitis complicated by localized or even generalized peritonitis.

The same method used in pelvic abscesses, and, in a general way, in neighboring suppurations of the intestine when *Bacillus coli* is present or abundant in the pus, may be of great service to the surgeon. Often such suppurations the point of departure of which is a lesion or traumatism of the digestive tract, are produced by the many micro-organisms from the intestine: anaerobes, enterococci, streptococci and at times even the *Bacillus fusiformis* and *Spirochaeta vincenti*. The presence of the colon bacillus

suggests the use of the anticolibacillary serum, but when anaerobes are associated therewith one must inject simultaneously the multivalent antigangrenous serum of H. Vincent and G. Stodel, as we have advocated in the treatment of gangrenous appendicitis, as well as the new antistreptococcal serum prepared by my method, which is particularly active even in septicemia verified by hamoculture.

Iliac abscesses before and after surgical intervention, often require subcutaneous injections of anticolibacillary serum, and even periglandular and perirectal abscesses. The serum in these affections, is a precious adjuvant for the surgeon. It is also useful to introduce a certain quantity into the field of operation.

Bacteriological study of suppurative salpingitis may demonstrate *Bacillus coli*. In such cases it is also very useful as has been shown by Chevassu, surgeon of the Cochon Hospital, to introduce the anticolibacillary serum into the field of operation, and to inject the same serum subcutaneously for 2 or 3 days (30 to 40 cubic centimeters per day). Thus one brings about a sharp drop in the fever and prevents an extension of the infection or its general dissemination through the blood stream.

The urinary tract, in woman as well as in man, is the seat of predilection of the colon bacillus. Basseler has found *Bacillus coli* in the urine of healthy subjects 18 times in 101 instances. But this observation should be verified. It is the same in the cases of William Estel who reports no less than 36 per cent of urinary colibacillosis in patients who are affected with constipation or intestinal affections.

In pathological states the bacillus appears in the urine, either primarily or secondarily in surgical affections, of the kidney, ureter, bladder and urethra and colibacilluria is extremely frequent. All maladies of the removal apparatus: lithiasis, hydronephrosis, cystic kidney, benign or malignant tumors, urethral stricture, prostatic hypertrophy etc. all encourage colibacillary localization. In some cases renal tuberculosis is complicated by the same infection and prognosis becomes particularly grave.

Explorations of the bladder and ureters may result in the ensemment of the urinary passages with various bacteria among which *Bacillus coli* is the most common.

These maladies, in which the colon bacillus has developed secondarily, justify above all, surgical treatment. It is upon such treatment that recovery depends. Serotherapy obviously can do nothing in renal or vesical calculus tumors prostatic adenoma urethral stricture etc.

However, in these maladies as long as the determining cause persists and keeps up the local infection serotherapy is an adjuvant to surgical treatment. And even when surgical treatment has already been instituted anti colibacillary serotherapy can be used as a necessary complement to such treatment, in combating the multiplication of the bacilli and against their becoming generalized which is so often a danger.

And so, according to Hunt's statistics 16.5 per cent of patients operated on for hypertrophy of the prostate, die of septicæmia. *Bacillus coli* is the common agent in these fatal infections. In the urological services of the Cochin Hospital in Paris the hospital of the Val-de-Grâce, the Hospital of Montpelier, etc., the serum is systematically utilized in this manner and very effectively.

It is customary to recommend also as a prophylaxis anticolibacillary serotherapy in patients who must submit to operation on the urinary tract when they are already infected. The injections of serum (20 cubic centimeters per day) are given on the day before the day of operation, and the following day. It is especially in nephrectomy renal or vesical lithiasis, or in the removal of the prostate that this prophylactic measure is indicated.¹

Primary suppurative colibacillus pyelonephritis,² recent or remote is usually cured in a few days by serotherapy, with or without lavage of the renal pelvis and bladder.

As is well known primary suppurative pyelonephritis is sometimes a complication in

various infectious states grippe, typhoid fever (II Vincent) malaria (II Vincent) bacillary or amœbic dysentery. They may accompany or follow colon bacillus septicæmia. I have shown that in 47.5 per cent of cases patients with primary pyelonephritis of *Bacillus coli* origin have in their history chronic appendicitis with or without operation. Stubborn constipation is a very common cause of colon bacilluria.

The colon bacillus may find lodgment and grow in the kidney when some mechanical obstacle hinders the passage of fecal material in the intestine (compression of the intestine by a tumor by pregnancy chronic enterocolitis intestinal ptosis etc.) It is the same when the passage of the urine is impeded or blocked by compression of the kidney, or the ureter or by renal ptosis.

In all these cases *Bacillus coli* has the intestine as its point of departure. It is moreover, frequently accompanied in the lesions and in the urine by other microorganisms of the same origin enterococcus and staphylococcus above all. I have more rarely found micrococcus tetrages, proteus vulgaris the streptococcus the bacillus of Friedländer, the pseudodiphtheria bacillus, certain anthracoides bacilli a very markedly Gram negative bacillus, certain anaerobes etc.

It is of primary importance, before practicing serotherapy to make a careful cytological and bacteriological study of the urine, and to verify by cultivation on appropriate media (lactose broth neutral red broth, litmus milk various sugars, etc.) the identity of the *Bacillus coli* isolated in the urine. A superficial examination may lead to errors of diagnosis of the micro-organism. According to my experience, in 18 per cent of cases, the urinary infection has been found to be of other organisms than the colon bacillus.

Leaving the intestine the renal infection is followed nearly always, as I have myself shown, by a blood infection, sometimes severe, sometimes light. It gives rise, at times, to extensive histological lesions, especially of multiple areas of suppurative glomerulitis and periglomerulitis, with enormous accumulations of bacilli in these infected foci and in the uriniferous tubules.

¹ When patients have already received therapeutic injections of horse serum, it is necessary to desensitize them by one or two preliminary injections of 1 cubic centimeter (or 11 necessary by three injections of 3 cubic centimeters) of serum, 3 hours before the principal injection of 20 to 40 cubic centimeters. I advise this even in adult subjects who have never previously been subjected to injections of horse serum.

² Without any of the renal, vesical, or ureteral lesions mentioned in the previous section.

Suppurative pyelonephritis due to *Bacillus coli* is fairly often complicated by cystitis. The urine contains a large number of damaged polymuclear leucocytes, desquamated cells of the renal pelvis, ureters and bladder and red blood cells.

The co-existence in the urine of the enterococcus, the staphylococcus and the micrococcus tetragenes, does not introduce, in my opinion any element of special gravity and places no obstacle to healing with use of anticolibacillary serum. In two patients suffering from old suppurative pyelonephritis following pregnancy the urine showed simultaneously the presence of *Bacillus coli* and the enterococcus. But anticolibacillary serotherapy brought about entire recovery. The enterococcus persisted for several months after the disappearance of the *Bacillus coli* and then it disappeared itself.

Other patients with serious forms of colon bacillus pyelonephritis, with association of the staphylococcus and the tetragenes were similarly completely cured after injections of serum.

The association of the streptococcus is much more serious. It obviously demands the use of mixed serotherapy by anticolibacillary serum and the new antistreptococcal serum.

Thus we see that the anticolibacillary serum has a very marked and very rapid curative effect on all forms of suppurative and primary pyelonephritis whether they be of long standing or recent. Serotherapy has cured infected patients with purulent urine which had existed for from 3 to 5 years, and even 10 years in one case that was reported to me.

It is not my purpose to publish here all these cases. I have taken only one example showing the rapid action of the serum in a very serious case. I have reported many others to the Academy of Medicine of Paris.

Mme. H., 42 years of age, in 1922 following her first pregnancy had subacute febrile enteritis which was probably the first stage of the infection which passed soon into a chronic condition. Her urine became purulent. Pyelonephritis complicated the course of her second pregnancy. The urine was filled with pus, numerous colon bacilli and staphylococci. Nine injections of autovaccine produced no result.

The labor was difficult, hemorrhage being abundant. From this time on her condition became one

of extreme gravity. The urine was highly purulent, and there were febrile attacks, renal pain, continuous phenomena of spasmodic enterocolitis, wasting, extreme anemia and complete adynamia. "The patient," said the physician who was treating her, "led a lamentable existence" (Prof. A. Lippens of Brussels). The condition had resisted all treatment and the most severe regimen. It had continued for 5 years.

In 1928, she was given four subcutaneous injections of 40 cubic centimeters each of anticolibacillary serum. The urine, which up to that time had been a bacterial reservoir and full of pus, became perfectly clear and sterile. "In a few days the patient was transformed. She had not felt so happy for five years (Dr. A. Lippens). All the morbid symptoms—pyuria, renal pain, chronic enterocolitis, fever, prostration, mental depression, etc.—disappeared completely in a few days. Several months afterward I was informed that her condition was still excellent. Her appetite had become normal, she had returned to her former weight "she had the bright and rosy expression of a woman in good health. The sterility of the urine has, since that time, continued. Examples of the same nature are today extremely common.

In a general way I have noted this apparently paradoxical fact that the graver the suppurative colibacillary pyelonephritis whether acute or of long standing and accompanied by very marked general phenomena,—fever symptoms of infection etc.—the more rapid is the recovery under the influence of the serotherapy. A great number of authors (Prof. M. Chevasu, Prof. A. Maisonneuve, Prof. Jeanbrau, Drs. P. Roger Petit, Leonhardt, Minet, Vénin, Trocmé, Dayras and R. Bernheim, Darget, F. Charles, and Nogues, P. Charpy, Grandineau, etc.) have published cases in which they have observed and verified these results.

Pyelonephritis of infants may as I have already said be unrecognized because the urine of infants is mixed with the other defects in the napkins. The condition may be marked by fever, diarrhea, vomiting, extreme wasting and rapid death. Bronchopneumonia is sometimes added to this syndrome, already so dangerous. But dealbumized anti-colibacillary serum injected subcutaneously in doses of 20 cubic centimeters during 5 or 6 days, caused rapid recovery of these little patients.

In adults treated by the serum it is often necessary to give, on the fourth and on the

seventh day of the treatment one or two lavages, first of the diseased renal pelvis a 1 per cent solution of silver nitrate being used, and second of the bladder with a solution of 1:1000 or 1:1500 because the antibodies carried by the serum in massive doses do not always penetrate into the urine. When the kidney is damaged it allows the passage of albumin, and with it antibodies in quantity sufficient to destroy the bacilli in the kidney pelvis and bladder. In these cases the urine becomes sterile about the eighth to the tenth day, and it is not necessary to practice lavage.

The example cited above shows that the serum alone may be sufficient to bring about sterilization of the kidney and of the urine. But antiseptic lavage of the renal pelvis and bladder assures the cure with more certainty because it destroys the residual bacilli which have persisted in these cavities.

Disinfection of the renal pelvis and bladder is not of itself sufficient to cure the patients because it is without action on the renal parenchyma. The majority of the patients whom I have observed were treated by this silver disinfection associated with vaccines, autovaccines, bacteriophages, chemical antiseptics etc. without any result. One patient aged 28 years who had submitted for 3 years to lavage of the renal pelvis and bladder continued to have very purulent urine. Five injections of serum brought about a complete cure, although the young woman had at the same time a mild degree of hydronephrosis.

The most resistant forms of urinary colibacillosis are those which are not accompanied by the presence of pus in the urine or in which the urine shows only rare polynuclear leucocytes. These are the forms that I have called 'stabilized colibacillosis'. However one may bring about their cure by prolonging the injections of serum for a week or more carrying out, during this period and afterward, the disinfection of the diseased renal

pelvis and bladder repeated two or three times. Anticollibacillary serotherapy is, then, the surest and most efficacious method of treatment of primary suppurative pyelonephritis whether acute or chronic.

Although it acts in all stages, it is preferable to inject the serum early in the pyelonephritis, when the phenomena are most acute, the urine is filled with pus and the fever is high.

It is useless or contra-indicated to associate with it any other chemical or vaccinal treatment. The use of vaccine and autovaccine or even the bacteriophage, has been known to provoke in selected cases the development of more resistant strains of colon bacilli. On the other hand by using other means of treatment one may precipitate almost fatally this very stubborn pathological state that I have called 'stabilized colibacillosis' which is the most resistant form of infection.

It is desirable to call attention to the necessity in patients recovered from pyelonephritis of remembering that the morbid state which induced the renal infection still persists. After such recovery one should watch the digestive tract and appendix, combat constipation, treat visceral and intestinal ptoses, consider the gall bladder, give advice as to prudent alimentary and general hygiene, and send the patient, after the cure, to the country or if the nervous condition permits for a sea voyage or possibly to certain of the hydro-mineral resorts such as those of La Preste or Capvern in France.

The persistence of the cause which in the first instance determined the invasion of colon bacilli may lead ultimately to a new infection of the kidney after a year or more, in subjects who have recovered bacteriologically.

Consequently a primary infection even when prolonged, of the kidneys by the colon bacillus does not necessarily confer after treatment, immunity of these viscera against a new attack of the same infectious agent.

CLINICAL SURGERY

FROM THE MEMORIAL AND THE FIFTH AVENUE HOSPITALS

THE ORIGINAL JANEWAY GASTROSTOMY

HAYES E. MARTEN M.D. AND WILLIAM L. WATSON M.D. F.A.C.S., NEW YORK, NEW YORK

IN 1913 the late H. H. Janeway published a description of his original technique for gastrostomy. The main principle of the Janeway operation is the construction of a narrow plastic tube from a full thickness flap of stomach wall. This tube leads from the stomach cavity to the skin and furnishes a gastric fistula entirely lined by mucosa rather than by granulation tissue as in most other methods. In his report of 5 cases, Janeway used a left, upper mid rectus incision and led the plastic tube out through the operative wound. He later modified this technique by using a longer midline incision between the xiphoid and the umbilicus and brought the plastic tube out through a stab wound in the middle of the left rectus just below the costal margin. This modification then became the standard technique at Memorial Hospital and was described by Quick and one of us in 1928 at which time we reported a series of 172 cases with a mortality of 18 per cent.

An analysis of the causes of postoperative death in this series revealed that many were due to complications resulting directly from the operative procedure such as infection and subsequent separation of the edges of the midline operative incision. Wound infection is, of course, both a more common and a more serious complication in the debilitated subjects in whom gastrostomy is indicated.

In our efforts to lower this postoperative mortality, we returned again to the original Janeway technique making a short (about 6 centimeter) incision through the middle of the left rectus, just below the costal margin delivering a portion of the anterior wall of the stomach, constructing the plastic tube, and fixing it in the upper angle of the wound. This change in technique has been followed by a remarkable improvement in the postoperative mortality. Since 1928, we have performed gastrostomy by this technique in 52 cases with a mortality of 3 (5.8 per cent). We believe that these 3 postoperative deaths were incidental

or due to the disease (carcinoma of the esophagus) rather than to the operation. The mortality will be discussed further later in this report.

The reasons for this improved mortality with the change in technique are quite readily understood. The body of the stomach or corpus ventriculi from which the plastic tube is to be constructed lies directly under the upper portion of the left rectus muscle and the adjacent costal margin. Therefore a short upper left mid-rectus incision will permit a more direct and an easier access to this portion of the stomach than a much longer midline incision. In the majority of cases, as soon as the peritoneum is opened, the anterior wall of the stomach is seen lying directly in view. With a sponge forceps a sufficient portion is delivered through the wound to permit the entire operative procedure on the stomach to be done outside the abdominal cavity. Since no retractors are required after the stomach is delivered, there is little discomfort and practically no surgical shock. After the construction of the plastic tube, its attachment in the upper angle of the incision and the closure of the operative wound is quickly accomplished in a few minutes. Since the whole procedure is done with a minimum exposure and a minimum manipulation within the abdominal cavity and of the wound edges, infection should seldom occur with good technique. Gastric contents, will, of course sometimes contaminate the wound edges with subsequent wound infection, but in our series never resulted in separation of the fascia and caused no mortality and a very slight morbidity.

The location and behavior of the operative incision is perhaps more important in this operation than in many others. Janeway abandoned the left rectus incision because of too frequent infection and breaking down of the wound with subsequent detachment of the plastic tube from its moorings, a complication which is avoided by keeping the incision short. In an attempt to avoid contamination of the operative wound and to in

Fig. 1. The operative incision is made through the middle of the left rectus beginning as high as possible at the subcostal margin. It should be kept short. Six centimeters usually is sufficient.

Fig. 2. The first incision is made in the longitudinal diameter near the lesser curvature. An Allis clamp is placed on the lesser curvature side.

sure the fixation of the plastic tube he brought the latter through a separate stab wound. In so doing the operative wound is best made in the midline since a right split rectus incision does not permit of easy access to the body of the stomach without too great length and considerable retraction and manipulation. In any case a midline incision must be at least 8 to 10 centimeters in length or even longer to permit the necessary manipulation for delivery of sufficient stomach and fixation of the plastic tube in a separate stab wound. This midline incision above the umbilicus is we believe the weakest in the entire abdominal wall from the standpoint of immediate healing. It is certainly far simpler to fasten the plastic tube in the operative wound but this is attended by far more danger of wound infection and subsequent serious complications unless the operative wound is kept short and is made through the strongest portion of the abdominal wall (the rectus muscle).

In our previous report, we also advised inserting the feeding tube through the pylorus, so that the feedings would be delivered into the duodenum for the first few days. The purpose of this procedure was to avoid distention of the stomach until healing was firm. With the present technique we insert the feeding tube into the stomach only and have found that our former precautions were entirely unnecessary and necessitated more intragastric and intra-abdominal manipulations

which tended to produce more surgical shock and infection of the operative wound from contamination by gastric and duodenal contents.

Other factors being equal we are convinced that the success of this operation depends upon keeping the operative incision short. In the average case there is not a great thickness of subcutaneous fat and an adequate portion of stomach can be delivered through an incision 6 centimeters in length. Such a wound does not require a great deal of separation of muscle fibers and is closed by 3 or 4 sutures. There is little lateral tension on

Fig. 3. A portion of the anterior wall of the stomach is delivered through the 6 centimeter incision. The dotted lines show the position and relative size of the intended flap.

Figs. 4 and 4A. The flap has been raised and the Allis clamp at the lesser curvature marks the point of beginning closure.

the wound edges and even though there is slight infection the fascial edges never separate and permit dislodgment and withdrawal of the plastic tube within the abdominal cavity.

INDICATIONS

Gastrostomy is indicated in all cases of persistent dysphagia in which complete relief cannot be expected within a reasonably short time. In dysphagia of benign origin such as peptic ulcer of the esophagus, syphilis, tuberculosis, or in burns following the swallowing of caustics the indications are too clear to require any special comment. Cardiospasm is almost always amenable to dilatation alone.

Practically all the controversy concerning the indications for gastrostomy is in carcinoma of the esophagus. We believe gastrostomy to be the best palliative treatment for dysphagia due to malignant stricture of the esophagus, hypopharynx or cardia and that this operation is attended by less risk, discomfort, and mental anxiety than is either bouginage or intubation. We also believe the average length of life to be greater in unselected cases. Bouginage is indicated in patients refusing operation, especially in malignant strictures of the upper half of the esophagus where the arrested ingesta do not ordinarily cause marked distention or sacculatation of the esophagus.

Gastrostomy puts the malignant stricture at rest and promptly overcomes malnutrition. No further painful or distressing manipulations are required to insure the continuation of proper alimentation. In both bouginage and intubation the

traumatic procedures which surely hasten the extension of the disease must be repeated every few weeks as long as the patient survives.

Those who favor bouginage or intubation emphasize the disadvantages of gastrostomy such as the operative risk, leakage from the stoma, and the discomfort of constantly wearing the feeding tube. These objections are perfectly valid in operations of the Wittel type but in the Janeway operation as herein reported, these objections have little or no comparative importance.

We have had no personal experiences with intubation but have used bouginage in 20 cases. The latter procedure is not possible in all instances, depending on the location of the stricture and its morbid anatomy. It is furthermore both distressing and painful in the majority and must be repeated at regular intervals. The same objections apply equally to intubation. In practically all cases in which we have used bouginage there comes a time after a few weeks or months when this procedure becomes so difficult or is accompanied by so much pain or bleeding that it must be discontinued or done at the risk of immediately fatal consequences. In such cases one is forced to witness death by dehydration or starvation since gastrostomy at this stage is a futile gesture.

If gastrostomy is to be done in cancer of the esophagus, the earlier the operation is performed the better. It should never be deferred until there is marked loss of weight and strength. If the patient is still able to swallow liquids, he may defer using the stoma for feeding purposes for a time. Its presence causes no discomfort. If length of life is the only consideration nothing but water

Fig. 5 The feeding tube has been inserted into the stomach. Partial closure of the mucosal layer has been effected.

should be taken by mouth after operation since a portion of swallowed food almost always remains above the stricture to ferment and decompose.

The technique is clearly outlined we believe in the accompanying illustrations and will therefore be quite briefly described. If there is even moderate dehydration the operation had best be deferred for 24 to 48 hours so that the lost fluids may be made up by several hypodermoclyses and by rectal administration. Local anesthesia is to be preferred. Many patients requiring gastrostomy are in such a state of inanition that general anesthesia is inadvisable. The operative procedure and intra-abdominal manipulation is so limited that it is seldom that the patient complains of much discomfort.

TECHNIQUE

Under local infiltration alone or combined with a subcostal block, an incision 6 centimeters in length is made through the middle of the left rectus beginning as high as possible at the subcostal margin (Fig. 1). Behind the rectus muscle at this point lie fibers of the transversalis muscle. These are either separated and retracted or partly cut through. A sphincteric action of these muscles was formerly emphasized but we question if it is of much importance in maintaining continence.

When the abdominal cavity is entered the anterior wall of the body of the stomach is usually seen lying directly under the wound. In some cases the stomach may be situated high or the costal margin unusually low and slow manipulation is necessary to stretch the gastrohepatic omentum sufficiently to allow partial delivery of the stomach. It is well to pull the stomach a little

Fig. 6 The mucosal suture has been completed. The serosal suture is partially completed. Note the clamp fixing the feeding tube to the end of the mucosal suture.

to the right so that the plastic tube is placed as far toward the cardia as possible without too much tension. Care should be taken that the plastic tube is constructed from the body of the stomach rather than from the pyloric antrum. In the latter case, leakage and discomfort after feeding are more common. A portion of the anterior wall near the lesser curvature about 8 centimeters in diameter is then delivered through the wound (Fig. 2) and packed about with wet lap sponges.

A rectangular flap about 3 centimeters long and $2\frac{1}{2}$ centimeters wide with its base toward the greater curvature and its free end at the lesser curvature is then outlined by Allis clamps (Figs. 2 and 3). The stomach wall is always contracted particularly in the transverse diameter when delivered and the flap will be found to stretch markedly and become 4 to 5 centimeters in length as the plastic tube is constructed.

The first incision should be made at the free end of the intended flap and parallel to the lesser curvature and as the stomach is entered an additional Allis clamp should be placed in the center of this incision on the lesser curvature side to mark the point of beginning closure (Fig. 3). From the extremities of this incision two others are made at right angles toward the respective clamps which mark the base of the flap (Figs. 3 and 4). As the flap is freed the two Allis clamps which mark its tip should be removed and replaced so as to grasp all coats of the stomach wall.

After the ligation of bleeders a No. 14 French catheter is placed within the stomach only and closure is begun at the clamp which marks the middle of the first incision at the lesser curvature continuing up the edges of the flap to form a gooseneck tube. We use an interlocked layer of No. 00 chromic to the mucosa and muscular

Fig. 7. Showing successive stages of fixation of the plastic tube and closure of the abdominal wound.

coats, and an interlocked Lembert suture of the same material to the serosa (Figs. 5 and 6). When these sutures are completed to the apex of the plastic tube, they are cut long and clamped so as to secure the gooseneck until it is sutured in place. The delivered portion of stomach is then returned to the abdominal cavity and the plastic tube is placed in the upper angle of the wound (Fig. 7). Closure of the abdominal wound is accomplished in the usual manner not too tightly about the tube which is attached to the external rectus fascia by two stitches of No. 0 chromic through the serosa only. The plastic tube should protrude slightly above the skin surface (Figs. 8 and 9). It is sutured to the skin by 4 sutures of silk. A vaseline dressing is applied about the catheter which is made to protrude through all layers of the dressing and adhesive so that the feedings may be given without removal of the dressings.

POSTOPERATIVE CARE

As soon as the patient is returned to the ward he is given 3 ounces of water through the feeding tube. Following this he is given 3 ounces of milk every 2 hours until the morning after operation when the amount is increased to 4 ounces every 2 hours. The following day 5 ounces every 2 hours and so on, increasing the amount of the feeding to 16 ounces. When the feedings have been increased to about 10 ounces, the interval is lengthened to 3 hours and later to every 4 hours, and finally all feedings are omitted during the nightly

period of rest. The caloric value of the feedings is increased by the addition of lactose eggs, and butter added on successive days beginning about the fifth or sixth day. Orange juice or tomato juice should be added about the same time.

The reason for beginning with small frequent feedings of plain milk is not because of fear of distention of the stomach but rather to avoid gastro-intestinal disturbances which may occur with too copious feedings in patients whose digestive tracts have become unused to digestion. An uncommon postoperative complication is diarrhoea, which may be fatal the gastro-intestinal tract apparently being unable to retain even fluids. In such cases, the feedings must immediately be reduced to the original quantity (3 ounces) of boiled milk with the addition of small doses of tincture of opium.

The patient may be safely allowed out of bed with a firm abdominal binder on the third to the fifth day depending chiefly on the pre-operative condition. The position and shortness of the operative incision are such that there is no danger of too early a strain on the incision.

When the skin sutures are removed the feeding tube is withdrawn and inserted only for feeding purposes. Until the nursing staff is familiar with the after-care of this operation it is safer to leave the feeding tube in place constantly the surgeon himself changing it every day or two until about 2 weeks after operation. Inexperienced attendants may misdirect the tube outside the tract and

Fig. 8. The completed operation showing the relative position of the operative incision, the stomach and the plastic tube.

force the feeding into the peritoneal cavity. After firm healing, there is no danger of this accident. There is no danger of closure of the stoma even if the tube be left out for months. In no case should a larger feeding tube than a No. 16 French catheter be used. Since all feedings must be liquid in any form of gastrostomy, there is no advantage whatever in a larger tube which will only tend to cause leakage by stretching the stoma. At the completion of a feeding when the tube is with drawn, firm pressure with a gauze sponge over the stoma for a minute, allows the fistula to contract and continence is usually entirely satisfactory and a single gauze sponge is sufficient to cover the stoma under the clothing.

While in the hospital the patient should be taught to insert the tube and feed himself. The caloric value of the daily feedings should be at least 3,000 calories, including the necessary vitamins. Many intelligent patients seem to derive a great deal of interest in the make up and calculation of the feedings. For the guidance of the average patient we furnish a mimeographed copy of the following instructions.

POSTOPERATIVE MORTALITY

In our series of 52 gastrostomies done by the present technique there have been 3 postoperative deaths (5.8 per cent), which we believe to have been incidental and due to the disease (carcinoma

Fig. 9. Healed condition after operation. Note that a small portion of gastric mucosa protrudes above the skin surface.

GASTROSTOMY FEEDING

Flowers of feeding	A liter			
	Milk	Milk sugar	Iron (malted)	Fresh eggs (raw)
6 a.m.	2 1/2 cups or 17 oz.	3 scant tbs.	1 t. p.	
8 a.m.	(8 oz. term)	1 ounce		
10 a.m.	17 oz.	3 scant tbs.	1 1/2 tps.	2
2 p.m.	7 oz.	3 scant tbs.	1 1/2 tps.	1
6 p.m.	17 oz.	3 scant tbs.	2 tps.	1
10 p.m.	17 oz.	3 scant tbs.	1 1/2 tps.	2

At 1 a.m. 1 dram (1 tsp.) iron and ammonium citrate

1. Insert tube only for feedings.
2. Make up each feeding fresh. Heat slightly before using.
3. Take feeding slowly—allow at least 10 minutes for each feeding.
4. Rest 10 minutes after each feeding.
5. Clean feeding tube with water after each feeding—do not boil.
6. Obtain from drug store:
 1. One No. 14 French catheter
 2. "Asepto" syringe with a tip to fit catheter
 3. Large can of Lactose (milk sugar)
 4. Iron and ammonium citrate, ounces 8, and take 1 teaspoonful in the 10 a.m. feeding
 5. One 8 ounce measuring cup.
7. If constipated, take one ounce of castor oil in the last feeding at night.
8. Take nothing by mouth except water. This may be taken in small amounts if it does not cause vomiting.
9. If stomach distress and nausea follow the feedings, the milk content should be reduced to 12 ounces for 2 or 3 feedings.
10. Any unusual symptoms or difficulties should be reported to the hospital.

of the *oesophagus*) rather than to complications resulting from the operative procedure. One patient had an uneventful recovery with primary healing until the ninth postoperative day, when he suddenly fell dead while walking about the ward in apparently good condition—probably a cardiac death. The second was admitted with complete dysphagia and symptoms of mediastinitis. X-ray examination showed the presence of a broncho-*oesophageal* fistula and bronchopneumonia. After 48 hours during which time fluids were forced by hypodermoclysis and proctoclysis, his condition improved sufficiently so that gastrostomy was thought indicated since the patient could swallow not even water. The postoperative course was fairly satisfactory for 12 days. He died on the fourteenth postoperative day and autopsy showed death to have been due to broncho-*oesophageal* fistula and bronchopneumonia. A third patient died on the fourth postoperative day from *oesophageal* hemorrhage probably from perforation of the aorta by disease.

Carcinoma of the *oesophagus* is a lethal disease and gastrostomy is not done in many cases until such terminal complications as perforation of the growth into a large vessel or bronchus are imminent. Such complications are apt to occur during the postoperative period and therefore gastrostomy if done for cancer of the *oesophagus*, will always be followed by a certain unavoidable per-

centage of postoperative deaths. Good statistics will, therefore, depend partly on chance and on as early operation as is possible.

The postoperative mortality in gastrostomy varies from 6 to 20 per cent as published by various authors. We believe that the lower figure is possible with the Janeway technique and the advocacy of operation as soon as the diagnosis is made.

SUMMARY

The advantages and technique of an improved original Janeway gastrostomy are described. This operation differs from that already published by Quirk and one of us, in that the procedure is done through a single 6 centimeter incision through the middle of the left rectus just below the costal margin. The fistulous tract from the stomach to the skin is formed by a plastic tube constructed from stomach wall. By this technique we have performed gastrostomy in 52 cases with a postoperative mortality of 5.8 per cent.

FROM THE CLINIC OF DR. PHILIP LEWIN, MICHAEL REESE HOSPITAL

THE GALEAZZI TREATMENT OF SCOLIOSIS

PHILIP LEWIN, M.D., F.A.C.S. CHICAGO

SCOLIOSIS is one of the oldest conditions described in medical literature. Hippocrates gave the generic term "scoliosis" to any twisted spine. An extensive literature much of which is repetition has been accumulated on the subject. The outstanding contributions have been made by such men as Schulthess, Wullstein, Lovett, Brackett, Abbott, Freilberg, Kleinberg, Hibbs, Steindler, Feiss, Calve, Buchman, Brewster, Risser, and Galeazzi.

The spine, a flexible weight-bearing column made of segments and already curved in one plane (anteroposterior) will not yield in another plane (lateral) without twisting. In this twist the vertebrae must turn away from the greatest weight and pressure, that is toward the convexity.

The etiology of scoliosis involves chiefly such factors as (1) heredity, (2) congenital anomalies of the spine, (3) pathological conditions of the vertebrae, (4) nutritional changes, (5) infections, (6) epiphyseal changes, (7) muscle disbalance, and (8) paralytic conditions. There is a large group of cases included under the term "idiopathic scoliosis."

Hibbs believed that in a great many more cases than were recognized the condition was due to infantile paralysis. Buchman believes that many are due to vertebral epiphysitis. Jansen attaches importance to irregularities in the attachments of the diaphragm.

Ferguson has been impressed by the apparently reciprocal relation between rotation and wedging of the vertebral body. With a curve of given degree in a given area of the spine he finds a definite amount of rotation unless wedging is present. With wedging there will be less rotation. Wedging appears to decrease the need for rotation.

In 1844 Bigelow advanced the principle that torsion rotation is illustrated by bending a blade of grass or a flat flexible stick in the direction of its width. The center rotates on its longitudinal axis to bend flatwise in the direction of its thickness. Likewise the spine laterally flexed turns on its vertical axis, to yield in its shortest, or anteroposterior diameter. This statement according to Smith implies (1) that there is a continuity of substance in the spine, (2) that the

spine is flat, (3) that the plane of flatness is in the frontal plane, and (4) that rotation is a concomitant element of lateral flexion.

When he began his investigations of the subject of scoliosis, Carey found that there was very little accurate anatomical and physiological knowledge concerning the mechanism of production of structural scoliosis. By two types of experimentation and investigation he has been able to make some interesting and important observations on the subject. The first method included a series of experimental amputations, selective muscle and nerve excisions, tail fixations, undernutrition experiments in young animals and observations on the dynamics of the histogenesis of muscles, bones and joints. The second method was the construction of a working model of the anatomical and physiological relations of muscle and bone levers of the normal human back. By this means results of experimental muscular imbalance registered at once on his spinal indicator, whereas by animal experiments he was forced to wait months and sometimes over a year for the same change to occur. This model is a most ingenious piece of mechanical construction. It enables one to demonstrate the greatest variety of structural mechanical changes and to visualize the normal and

abnormal dynamic equilibrium of the musculature of the body as a whole

Carrv believes that imbalanced action of bilateral antagonistic musculature resulting from undernutrition or malnutrition during the first decade of life will explain many cases of idiopathic scoliosis. He found that there are numerous possible combinations of muscular imbalance. With only 13 pairs of spinal muscles there are more than 67 million possible combinations of muscular imbalance resolved by the mathematical formula (2^I) . There are 144 muscles directly attached to the movable spine. It is impossible

to conceive the results of multiplying out to the 144th power

When I told Dr. Steindler in 1915 that I was going to Europe, he advised me to visit Galeazzi at Milan. At Manchester England I met Platt who spoke very favorably of the method. Then Delistah of Venice recommended it. In 1929 I visited Galeazzi again. In May 1931 I made my third trip. In 1928 I demonstrated the method before The Clinical Orthopedic Society in Chicago.

Through the efforts of Dr. D. H. Levinthal, the Ruth Lodge of Chicago purchased the apparatus

at a cost of one thousand dollars and presented it in 1930 to Michael Reese Hospital. I began using the apparatus in September 1930. Dr. Levinthal and I have worked with the machine individually and together.

I wish to outline the general considerations of a method of treating the difficult problem of scoliosis which has been found to be highly successful in the originator's hands. This is a preliminary report based upon observation in Galeazzi's clinic in Milan in 1925, 1929 and 1931 and in my own clinic.

The method may be described as follows. The patient is placed under an intensive preparatory

mobilizing treatment for a long period varying with the degree of rigidity of the spine. Special apparatus and exercises are used in this preparatory treatment. Accurate tracings are made by the Schultze method as well as plaster-of-Paris shells and models. Then one proceeds to correct the deformity by means of the apparatus herewith illustrated. There are two independent units: one which secures the shoulder girdle and the other the pelvic girdle. The patient is placed on a raised platform within the apparatus, with the trunk horizontal and hips and arms flexed so that the spinal column is suspended from two end buttresses; that is, he assumes the position

Fig. 10. Pelvic and shoulder girdles complete. Ready for deflection and derotation.

Fig. 11. Lower back deflected and derotated.

Fig. 12. Cast almost complete, showing traction bands still *in situ*.

Fig. 13. A patient with right structural scoliosis corrected in Galeazzi apparatus. (Courtesy of Professor Galeazzi.)

of a quadruped. By varying the distance between the two end units and their relative heights above the ground, it is possible to place the spine in the most favorable position for correction. When this position has been obtained, the two end units are secured, so that the apices of the thoracic and lumbar curves correspond with the centers of the rotatory mechanism which are indicated by two nuts on the floor of the apparatus. A plumb line is used for this purpose.

The apparatus permits independent rotatory movement of the two end units around a vertical axis, which accomplishes lateral deflexion of the spine. It also allows rotatory movements around the longitudinal axis of the spine producing derotation and detorsion.

The scoliotic spinal column is secured at its two ends by the application of two plaster-of-paris sections, including the pelvic and shoulder girdles. By means of a three tailed bandage applied over the apex of each curve and held by an assistant so as to act as fulcrums, one slowly begins to correct by means of deflexion and derotation against the fixed shoulder and pelvic girdle sections. These are then united by the third plaster-of-paris

Fig. 14. Roentgenograms of patient with right structural scoliosis corrected in Galeazzi apparatus. See Figure 13. (Courtesy of Professor Galeazzi.)

section. The principle is analogous to the correction of a club foot by the application of three plaster cuffs.

The cast extends from points high on the shoulders to others below the greater trochanters. Windows are cut out over the concavities of the curves. When the cast is complete, the patient stands in a flexed position and walks with his body flexed toward the convexity in a manner similar to but not quite so severe as in, the Abbott method. These casts are changed every 3 months. The total duration of the cast period is from 18 to 36 months.

The chief virtues of the treatment are in correction by deflexion and derotation rather than by means of direct force. The key to the correctability of the spine lies in a long preparatory mobilizing treatment. Galeazzi uses a mobilizer similar to the apparatus used for correction.

Galeazzi has obtained correction even in cases of rigid structural scoliosis. He has used this method in the treatment of several hundred severe, rigid cases of scoliosis with excellent results, as demonstrated by roentgenograms which have disclosed definite, and he believes, permanent correction of the vertebral torsion. He uses celluloid jackets to maintain correction.

It is not my purpose to compare various methods of treatment of scoliosis. I merely wish to describe one method. I have used the Abbott method under Ridlon, Porter and Calot. I have used the original Hibbs traction method. I

have had a limited but very favorable experience with the Risser method which probably is the best in America or possibly the world today. It has the advantage that it is simple and not expensive.

I have made some modifications in the technique since it was described in an article which Galeazzi wrote at my request and which appeared in the *Journal of Bone and Joint Surgery* for January 1929.

The disadvantages of the method include (1) the cost of the apparatus, (2) the long period of preparation by means of special apparatus necessary to accomplish good results, (3) the difficult technique of application and (4) the long after treatment.

The illustrations were made at the same time a moving picture film was prepared to illustrate

Galeazzi's method. The subject was a patient of Dr. Levinthal.

SUMMARY

After an intensive preparatory mobilization period the patient is placed on a small elevated platform and the pelvis is secured firmly. He bends at the hips and shoulders with hands supported on uprights and forehead on a rest, i. e. he assumes the position of a quadruped. His pelvic and shoulder girdles are secured by sections of plaster of Paris. His torso is then deflexed and derotated. The two sections are united by a third.

OLD TRAUMATIC DISLOCATION OF THE HIP

WITH SPECIAL REFERENCE TO THE OPERATIVE TREATMENT

LEO J. MILTNER, M.D. AND F. E. WAN, M.D. PEIPING, CHINA

From the Division of Orthopedic Surgery, Department of Surgery, Peiping Union Medical College

SIXTEEN cases of old traumatic dislocation of the hip have been treated at the Peiping Union Medical College during the past 10 years. The time of postoperative observation has extended from 6 months to 9 years, with an average of 2 years for all cases. Since this condition is seen rarely in most clinics, a review of the subject and a presentation of cases seems appropriate.

PATHOLOGICAL ANATOMY

In order to understand fully the pathological anatomy of old dislocations of the hip (Fig. 1) it is necessary to discuss the changes which occur during as well as after the original trauma.

Posterior dislocations. The position most favorable for the posterior type of dislocation is one of flexion, adduction, and internal rotation. Ordinarily the capsule is torn through in the postero-inferior portion. As the head of the femur passes backward and upward it may tear one or more of the small rotator muscles. The quadratus femoris lies directly in the path of the head during dislocation; hence it is injured very frequently. The obturator externus, obturator internus, the gemelli, and even the pyriformis may be injured similarly in severe cases. Occasionally the head may push its way between the obturator internus and the pyriformis, or between the pyriformis and gluteus minimus, without trauma to these muscles. If the dislocation occurs below the tendon of the obturator internus, the head then passes laterally and upward so that the tendon lies between the neck of the femur and the ilium (dislocation below the tendon—Bigelow—Fig. 2). In the same way the tendon of the pyriformis may be wound around medial to the neck of the femur (Fig. 3). An intact condition of the γ ligament is responsible for producing the characteristic position of the thigh after dislocation, i.e., flexion, adduction, and internal rotation. In rare instances the γ ligament may be ruptured completely with the result that the thigh is then held in a position of flexion, abduction and external rotation—the so called everted posterior dislocation.

Contractures of the pelvic femoral muscles soon take place in the untreated case. As time goes on a new capsule of scar tissue forms around the head of the femur fastening it securely to the side of the

pelvis. Within 4 weeks time ligamentous shreds, fat, and new connective tissue fill the acetabulum. This mass of tissue adheres firmly to the cartilage so that, after 6 weeks, sharp dissection is necessary for its removal. As early as 1893 Volkmann recognized these changes following experimental dislocations in rabbits and dogs. He found that after 3½ weeks new connective tissue adhered firmly to the cartilage and that after 8 or 10 weeks the joint was filled with a hard fibrous mass which in itself prevented reduction. One of the writers (L. J. M.) repeated these experiments with essentially the same findings.¹ Similar clinical observations have been made by surgeons during the operative treatment of congenital dislocations. In several instances redislocation of the hip occurred shortly after open reduction and, upon re-operation 3 to 4 weeks later the acetabula were filled completely with adherent soft tissues.

Changes in the head of the femur occur almost routinely as a result of the original trauma or the pressure forces which follow dislocation (Fig. 4A). If a piece of the femoral head has been crushed or broken off during the dislocation the late findings are those of roughening and partial disappearance of the cartilage—changes simulating advanced arthritis. In the very old cases, the head may be flattened or roughened because of weight bearing in a deformed position.

Anterior dislocations. In the anterior group of dislocations, displacement of the head of the femur most commonly is against the obturator foramen, with abduction, external rotation, moderate flexion, and apparent lengthening of the thigh. The head of the bone tears through the capsule in the antero-inferior portion and lies on the obturator membrane where it is partly surrounded by the torn fibers of the obturator externus muscle. The ligamentum teres may be stretched or completely torn through. The small external rotator muscles of the hip are drawn over the posterior edge of the acetabulum. In all old anterior dislocations whether obturator, pubic, or perineal in type, the acetabulum fills with a mass of scar tissue just as it does in the posterior variety. Complete tearing of the γ -ligament also is very unusual in the anterior type. In late dis-

¹Unpublished work.

locations of either anterior or posterior type an unusual amount of new bone may form around the displaced head (Fig. 4B).

OPERATIVE TREATMENT

Preliminary skeletal traction. In late posterior dislocations traction as a preliminary step before reduction by either the closed or open methods is a procedure which cannot be overemphasized. This means the contracted structures are stretched gradually until the head of the femur has been pulled down to the level of the acetabulum (Figs. 5A and 5B). As a result the amount of force necessary to effect reduction and the local trauma produced at the time of operation becomes much less. In cases of more than 1 month's duration the writers advocate skeletal traction with a Steinmann pin through the lower end of the femur. (For technique see Case 1.)

Closed reduction. Most traumatic dislocations of the hip may be replaced by the closed method if the duration is less than 4 weeks. Following this period of time the difficulties of reduction gradually increase so that, after 2 months forceful maneuvers are apt to cause fractures of the upper portion of the femur. Consequently, if closed reduction is attempted between the fourth and eighth weeks it must be performed with great caution and, if unsuccessful, open arthrotomy should be employed. Careful study of stereoscopic roentgenograms will help to determine the advisability of late manipulation. Such study is important since the original trauma may have caused crushing injuries to the head of the femur and any great external force will only effect more damage. A description of the standard technique of closed reduction is not within the scope of this paper.

Open reduction. Studies by Bigelow, Maigne, Allis, and others of the pathological anatomy of dislocations of the hip led surgeons to a knowledge of the possibilities of open operation. The first arthrotomy to effect reduction of an old traumatic dislocation is usually accredited to Pott (1882). Since that time successful operations have been surprisingly few both because of the rarity of the condition and because of the technical difficulties involved. Buchanan collected from the literature, up to 1920, 49 cases reduced successfully by arthrotomy and added one of his own. The largest individual series belongs to Dollinger (3) who in 1925 reported results obtained by arthrotomy in 29 cases of inveterate traumatic luxations. In his group twenty-one hips were replaced completely. Difficulties in reduction necessitated resection of the femoral head in 7 cases and osteotomy in 1 case.

Two methods of approach have been used for old posterior dislocations: namely, the posterior one of Langenbeck and Hoffa and the anterior one of Smith-Petersen. Dollinger prefers the posterior method which is thus briefly described. An incision is made from the postero-inferior spine of the ilium to the base of the greater trochanter or on down to the insertion of the gluteus maximus. The fibers of the gluteus maximus muscle are split longitudinally, exposing the secondary capsule which surrounds the head of the femur and holds it to the pelvis. The secondary capsule is opened and by forceful internal rotation the head and neck of the femur are swung anteriorly and away from the acetabulum. In the ordinary dorsal dislocation the scarred obturator internus (gemelli) and pyramidalis muscles are now exposed. These muscles may lie between the neck of the femur and the pelvis and stretch across the upper and outer aspect of the acetabulum. Myotomy of these muscles is usually necessary to give full access to the socket of the hip joint. After the removal of all of the scar tissue from the acetabulum, the head of the femur is replaced by circumduction and traction.

Dollinger also uses the same approach for anterior dislocations (obturator) of the hip. In this type access to the acetabulum is blocked by the greater trochanter and the muscles already mentioned; consequently resection of scar tissue, myotomy, and inward rotation of the femur are necessary.

The anterior route was used in all except one of the cases reported in this paper. The incision is started at the middle of the iliac crest, continued forward until the anterosuperior spine is reached and extended downward along the anterior border of the tensor fasciae to below the level of the symphysis pubis. After the periosteal origins of the gluteus minimus and part of the gluteus medius have been stripped loose the upper edge of the acetabulum comes to view. Further dissection is made between the sartorius and tensor fasciae until the rectus femoris and iliopsoas muscles are seen. Myotomy of these muscles and resection of scar tissue allow complete exposure of the socket. The safest approach to the head is made by subperiosteal dissection along the upper end of the shaft and the neck until the secondary capsule is opened widely. The thigh is now rotated externally, causing the head of the femur to point laterally. This tightens the scar tissue which stretches between the neck of the femur and the pelvis. These cicatricial bands are severed transversely. Reduction of the hip may be accomplished by traction and manipulation.

Fig. 1. Schematic drawing which illustrates the various positions of the head of the femur in dislocations of the hip. According to Allen's classification a line drawn from the anterosuperior spine of the ilium through the center of the acetabulum divides such dislocations into two main groups. All anterior to this line are designated as anterior dislocations (obturator, pubic, subpubic, and perineal) and all posterior to this line are designated as posterior dislocations (ischiatric, acetab, and high dorsal). (Redrawn from Wilson and Cochrane.)

For obturator dislocations the anterior or if occasion demands, the combined anterior and median approaches offer good exposure. Recently the writers used a modification of the anterior approach for an obturator dislocation of 2 years' duration (Fig. 6). The incision was started at the junction of the anterior and medial thirds of the crest of the ilium, continued forward to the anterosuperior spine and then extended downward along the medial edge of the sartorius muscle to the apex of Scarpa's triangle. The gluteus minimus, rectus femoris, and sartorius muscles were retracted laterally. This allowed ready access to the acetabulum. The scar tissue was removed from the socket following which the upper edge of the head of the femur was exposed. It was necessary to chisel away a shelf of new bone which had formed at the junction of the obturator foramen and the acetabulum. Further dissection allowed exposure of the capsule of scar tissue which surrounded the neck. This was cut trans-

versely. Forceful adduction and external rotation brought the head into full view. Following its long period of contact with the margins of the obturator foramen the head had become somewhat pear-shaped and roughened with hypertrophic flanges of bone at the junction with the neck. Since the acetabulum also was roughened it was believed that if the head were returned to the socket in this condition an arthritic hip joint would result. In the hope of overcoming this almost inevitable sequela the head was chiseled down to one-third its former size and then maneuvered into the acetabulum. In a case of 3 months' duration Dr. Steindler used both the median and anterior approaches. The median incision (Ludloff) was made along the inner border of the adductor magnus. The head was approached by dissection between the adductor longus and adductor magnus muscles. Myotomy of these muscles was necessary to allow good exposure of the scarred mass surrounding the head. The secondary capsule was split and the thigh was abducted and externally rotated, making the whole head and neck visible. Exposure of the acetabulum by this route was extremely difficult. A second approach, which was that of Smith-Petersen, was then made. The scar tissue was removed from the socket and the hip was manipulated into normal position.

While complete reduction by open arthrotomy is the goal sought in all cases of old dislocation the surgeon may be forced to accept certain alternative procedures such as the "shelving" operation, resection of bone, arthrodesis, or in exceptional instances, he may be content with simple osteotomy to correct the deformity.

"Shelving" operation (Koenig, 1891; Albee, 1915). The shelving operation consists in the formation of an efficient bony roof over the displaced head of the femur. The shelf is made by turning down plates of bone from the outer surface of the ilium for the purpose of affording stability and preventing pain. Henderson reported a case in which during arthrotomy it was impossible to bring the head of the femur far enough forward and downward to replace it in the acetabulum. Hence with a Murphy reamer such as is used for arthroplasty a new acetabulum was made a little higher than the old one. In addition flaps of bone were turned down over the superior surface of the head. Four months later roentgenograms showed an excellent new acetabulum with a well formed shelf. Motion was fair with flexion 140-150 degrees. He expected a stable hip as an end-result. Shortening in this case was about 3 centimeters; previous to operation it had been 8 centimeters.

Fig. 2. Sketch illustrating the mechanism of posterior dislocation below the tendon of the obturator internus. The femur is in a position of flexion, internal rotation and adduction. In this type the head of the femur breaks through the posterior inferior portion of the capsule below the tendon of the obturator internus. Note that the head in rotating upward passes lateral to this tendon. The head may also pass lateral to the tendon of the pyramidalis, B. In this event both tendons, A and B are wound around the neck of the femur and therefore lie between the neck of the femur and the flum.

Fig. 3. Drawing to represent a further stage of dislocation into the high dorsal position. Part of the head and neck of the femur (C) has been cut away so that a better view of the tendons may be obtained. The obturator internus, I and I' and pyramidalis tendons, B and B' pass between the neck of the femur and the pelvis, and wind anteriorly around the neck to reach their insertions into the region of the great trochanter.

Resection (Hoffa) Dollinger believes that resection of a portion of the head of the femur or even of the whole head, neck and great trochanter may be done if reduction is extremely difficult, or if pressure symptoms are present in the distribution of the sciatic nerve. Following this procedure the upper end of the femur is placed in the acetabulum and partial fibrous ankylosis with good position of the hip is the usual result.

Fusion Arthrodesis of the hip may be the operation of choice in very late cases especially when the musculature is atrophic and contracted. It may also be indicated in cases showing a large amount of new bone at the site of displacement. This procedure should result in a permanent relief from pain, deformity and instability of the hip.

Osteotomy Simple osteotomy for the correction of deformity may be advisable in patients who are old or weakened and who would be unable to withstand the rigors of a more severe operation. Again osteotomy may find an indication in those

cases wherein roentgenograms show that complete reduction would be technically impossible. Figure 4 shows a case of 1 year's duration in which an unusual amount of bone had formed in the torn soft tissues. In this instance osseous bridges actually connected the region of the acetabulum with the newly formed capsular structures surrounding the dislocated head of the femur. The femur was almost completely ankylosed in a position of 110 degrees flexion, 20 degrees abduction and 20 degrees external rotation. Because of the firm and painless fixation of the upper end of the femur a subtrochanteric osteotomy was proposed but the patient refused treatment.

It is also suggested that the Lorenz Baeyer (8) bifurcation operation may find an occasional application. This method has recently received favorable comment by Hackenbroch and others in cases of irreducible congenital dislocations of the hip. This operation aids in the correction of instability, pain, and limp.

Fig. 4A. Traumatic dislocation of 10 years' duration. (Patient 35 years of age, untreated.) Note well shaped secondary socket which has formed on ilium posterior and superior to primary acetabulum (arrows, the rim of acetabulum). Head of femur appears flattened and roughened.

Fig. 4B. Roentgenogram of an everted ischiatic dislocation of 3 years' duration. Note the extensive calcification of the capsular structures which surround the head. Approximately 25 degrees of flexion motion was present in the hip.

Arthroplasty Arthroplasty may be indicated if during open arthrotomy, the femoral head is seen to be roughened and arthritic and fibrous ankylosis seems probable or if after successful open reduction, the hip continues to show marked pain and limitation of motion in the presence of good musculature.

From the statistical table it may be seen that complete reduction was accomplished in every case. Some of the operations were necessarily prolonged and severe but on the whole the results were very encouraging. Follow up records show that the results were excellent in 8 cases, good in 1 case, fair in 4 cases and poor in 2 cases. In an evaluation of the success of the treatment in this series it should be repeated that the duration of the dislocations varied from 3 weeks to 4 years, with an average period of 7.7 months in all cases studied.

In order to emphasize interesting observations made during the surgical management of these cases the following records have been selected for detailed report. The first case illustrates the value of skeletal traction as a preliminary step to open arthrotomy for old posterior dislocations. The most serious complications of arthrotomy were the development of secondary infection (3 cases) and injury to the sciatic nerve (1 case). The danger of fracture during late manipulation is

shown in Case 4. Another history illustrates the development of marked hypertrophic arthritis several years after open arthrotomy. It was interesting to note that 80 per cent of the cases showed similar changes in follow up roentgenograms. Usually the arthritis was of mild nature and caused pain only upon overuse of the hip. Case 6 is added because of the very unusual etiology. In this instance a rifle bullet passed through the medial portion of the head, and caused a fracture of the posteroinferior rim of the acetabulum. It is believed that the combination of capsular tear and fracture allowed subsequent muscular pull to produce the dislocation. Fortunately infection did not follow so the dislocation was treated in the usual manner. The last 2 cases (shown only by photographs and roentgenograms, Figs. 11 and 12) are illustrative of excellent results which are obtained following open reduction.

THE VALUE OF SKELETAL TRACTION BEFORE OPEN REDUCTION

CASE 1 A Chinese male, aged 35 years, was first seen on April 2, 1931. The entrance complaint was pain and deformity of the right hip of 80 days duration. The general physical examination and laboratory tests of blood and urine gave normal findings. The right thigh was held in a typical position of posterior dislocation—flexion (45 degrees), adduction (30 degrees) and internal rotation.

Fig. 5A. Roentgenogram showing an old traumatic dislocation of the left hip (4 years). The head of the femur is in the high dorsal position.

The great trochanter was 2.5 centimeters above Rose-Nelson's line and the measurements of Bryant's triangle were compatible with dislocation. There was approximately 4 centimeters of actual shortening. The roentgenographic report confirmed the clinical impression: in addition there was a displaced fracture of the postero-inferior portion of the acetabulum.

Fig. 5B. This roentgenogram (same case shown in Fig. 5A) was taken 3 weeks after the application of skeletal traction to the lower end of the femur. The head of the femur might appear to be within the acetabulum but it actually lies directly posterior to the socket. The dark shadow represents the upper end of the Thomas ring.

On April 10, 1931, a Steinmann pin was inserted through the lower end of the right femur. A Thomas splint was applied and traction was maintained for 10 days. The traction was started at 5 pounds and increased gradually up

Fig. 6. An obturator dislocation of 2 years' duration. Note the extensive formation of new bone in the obturator foramen. This hip was reduced by open arthrotomy through a modified Smith-Petersen incision.

Fig. 7. Roentgenogram of an old traumatic dislocation which became infected following open reduction. This picture represents the late healing stage of suppurative arthritis.

Fig. 8A. Roentgenogram showing an old traumatic dislocation of the obturator foramen (duration—years). Note that the head is completely displaced through the foramen. Also note the calcified material which surrounds the head—an indication of the primary acetabulum.

Fig. 8B. Roentgenogram from the same case shown in Figure 8A following closed reduction. A portion of the head of the femur remained within the secondary socket. The intact portion of the head was placed successfully in the acetabulum.

to 20 pounds. At the end of this period of time the head of the femur had been pulled down to the level of the acetabulum. On April 20, 93, open reduction was performed with the aid of spinal anesthesia. A Smith-Petersen incision was used. Upon dissection toward the hip joint, dense scarred mass of iliopectineus muscle was found stretched over the inferior half of the acetabulum. This was cut through and the rim of the socket was exposed. The acetabulum was filled with remnants of capsule, fat, and newly formed connective tissue. After this was removed, intact cartilage was seen. The head and neck of the femur were then exposed by an incision through the secondary capsule. Forceful external rotation stretched back the scar

tissue bands of the obturator internus and piriformis tendons since both of these structures were wound around the neck of the femur and therefore lay between the posterior edge of the acetabulum and the neck of the femur. Following tenotomy of these tendons and further cutting of the scar tissue, the head of the femur was reduced rather easily. The relative ease of reduction was accredited to the

Fig. 9A. Roentgenogram of an old ectatic dislocation (—months duration) before operation. Note the fracture of the posterior rim of the acetabulum.

Fig. 9B. Roentgenogram of the hips shown in Fig. 9A, 9 years and 9 months after successful open reduction. Note the presence of marked hypertrophic arthritis. Excellent function of the hip was present.

Fig 10A Pre-operative roentgenogram of an old gun shot fracture-dislocation of the hip (80 days). Apparently the bullet passed through the head of the femur and fractured the posterosuperior rim of the acetabulum.

stretching and relaxation of the soft structures which followed preliminary skeletal traction. The wound was closed in the usual manner and a long leg hip spica cast was applied with the thigh in 25 degrees abduction.

The patient ran an uneventful postoperative course. The cast was removed 2 weeks after operation. Physiotherapeutic treatment consisting of baking, massage and active and passive motion was started and continued for 6 weeks. At the end of this time the patient was able to bear weight upon the hip without pain. Active motion was present to the extent of 80 degrees flexion, 45 degrees abduction and 30 degrees adduction. Six months later the patient stated in a follow-up letter that motion and strength of the hip were improving very satisfactorily.

In the earlier cases of posterior dislocation in this series preliminary skeletal traction was not employed and as a result many difficulties were encountered in effecting reduction even after the head and the acetabulum had been isolated. In most instances efforts at manipulation and traction failed and the head was replaced only by the use of a steel lever. Crushing injuries of the head frequently followed the application of this instrument. In the hope of overcoming such difficulties preliminary skeletal traction (technique of Van Gorder) was employed in the latter 5 cases and, in each instance, it was possible to pull the head down to the level of the acetabulum before open arthrotomy. The traction was maintained for periods of time varying from 1 to 5 weeks. The weights were gradually increased from 5 pounds up to 20 or 25 pounds. Measurements of the extremity were made daily and when the length approached normal roentgenograms were taken to determine accurately the position of the

Fig 10B The same hip shown in Figure 10A after 10 days of skeletal traction. This picture was taken before the open arthrotomy. It shows that the head has been pulled down to the level of the acetabulum. Stereoscopic views revealed that the head was still dislocated posteriorly.

Fig 10C The same hip shown in Figures 10A and 10B 5 weeks after open reduction. Aseptic absorption of part of the head may be seen.

Fig. 1. Illustrations of a case of posterior dislocation of the hip with excellent result following open reduction. A Pre-operative roentgenogram of left hip, illustrating a posterior dislocation of 8 weeks' duration. B Post

operative roentgenogram of the same hip. Photographs C, D, E, and F show motion of the left hip 3.5 years after operation.

femoral head. If the X-ray films showed that the head had been pulled down to the level of the acetabulum the hip was then considered ready for open reduction. By the use of this method the trauma of open arthrotomy was decreased to a great extent and in each of the latter 5 cases

complete replacement was accomplished by gentle manipulation (Figs. 5A and B and 10A and B).

THE DANGER OF SECONDARY INFECTION

CASE 2. A Chinese male, 41 years of age, was first seen on March 23, 1935. The entrance examination was ex-

Fig. 12. Illustrations of a case of posterior dislocation of the hip with excellent result following open reduction. A Pre-operative roentgenogram of the dislocated right hip

(one year) B Postoperative roentgenogram of the same hip Photographs C D E, and F show motion of right hip 3 years after operation

essentially negative except for a posterior dislocation of the left hip which was of 8 months' duration. The left lower extremity was in the characteristic position (flexion, adduction and internal rotation) and weight bearing was moderately painful. Roentgenograms showed complete backward dislocation of left femur head lying against ilium above acetabulum. A small amount of new bone was seen in secondary capsule surrounding the head of femur

Open reduction without preliminary traction was performed with the patient under ether anesthesia. A Smith-Petersen approach to the hip joint was made: the incision extending from the anterosuperior spine of the ilium downward along the lateral edge of the sartorius muscle and backward along the crest of the ilium. Dissection was continued between the sartorius and rectus femoris and between the ilium and the periosteal origins of the gluteus

TABULATION OF CASES
Average Duration of Postoperative Observation—3 1/2 years

Age, sex	Duration of dislocation	Type	Complications of dislocation	Method of reduction	Result
28 M	mo	Posterior (scapular) Right side	Linear fracture of head of femur. Chip fracture of posterior rim of acromion. Septocapsular (X) fracture of right femur	Closed reduction (Dagbiew). Septocapsular fracture treated by skeletal traction	Excellent. Complete reduction of hip. Six months later hip showed 75 per cent of normal motion. Knee showed 70° flexion with artificial pass on over one
20 M	4 1/2 mos.	Anterior (clavicular) Right side	Intra-articular dislocation of head with new bone formation	Closed reduction (reversed Dagbiew). Manipulation prolonged and difficult, followed by large hematoma	Fair. Part of femoral head fractured and transgressed portion of head lodged in acromion. Fibrous ankylosis in good position. One year later considerable pass on over one
21 M	3 1/2	Posterior (scapular) Left side	None	Closed reduction (Dagbiew)	Excellent. Motion almost complete and painless one month after reduction
3 M	2 1/2	Posterior (scapular) Right side	None	Closed reduction (Dagbiew)	Excellent. Motion almost complete and painless 3 months after reduction
20 M	6 mos	Posterior (high dorsal) Right side	None	Open reduction. Posterior approach. Exposure of acromion very difficult. Manipulation during arthroscopy caused crushing injury to head	Fair. Reduction complete. Partial fibrous ankylosis present after 6 mos. Considerable pass on over one. Followed for 6 years. Chronic pain and disability. Observed 3 1/2 years
41 M	8 1/2 mos	Posterior (high dorsal) Left side	Some new bone formation about dislocated head	Open reduction. anterior approach	Fair. Reduction complete but secondary infection (posttraumatic) followed. Two years later hip analyzed in good position. Chronic pain and disability. Observed 3 1/2 years
27 M	1 1/4 mos	Posterior (scapular) Left side	Chip fracture of posterior aspect of acromion	Open reduction. anterior approach	Fair. Reduction complete but secondary infection (posttraumatic) followed. After one year analyzed in good position with painless weight bearing. Observed 4 years
40 M	1 mos	Posterior (scapular) Left side	Healed fracture of head. Marked osteoporosis	Open reduction, anterior approach. During arthroscopy head of femur bruised	Good. Reduction complete. Partial fibrous ankylosis. Function of hip good. Observed 2 months
30 F	1 mos	Posterior (scapular) Left side	Chip fracture of posterior superior acromioclavicular rim	Open reduction, anterior approach	Excellent. Reduction complete. Motion and function 95 per cent after one year. Observed 3 years
40 F	mo	Posterior (scapular) Right side	None	Open reduction, anterior approach	Excellent. Reduction complete. Patient developed usual range of painless motion. Observed 2 months
33 M	1 mos	Posterior (scapular) Left side	Bullet struck head of femur causing posterior dislocation of hip with fracture of head and exposure rim of acromion. No infection	Pre-operative skeletal traction very effective. Open reduction, anterior approach	Excellent. Reduction complete. Fibrous ankylosis of hip in good position. No infection. Observed 4 months
28 M	mo	Posterior (high dorsal) Right side	Chip fracture, posterior rim of acromion	Pre-operative arthrogram (Bock's) ineffective. Open reduction, anterior approach	Excellent. Reduction complete. Almost normal range of motion. Slight traumatic arthritis present after 3 mos
28 M	mo	Posterior (scapular) Right side	Marked osteoporosis of head and neck. Some flattening of the head probably due to old crushing injury	Pre-operative skeletal traction very effective. Head osteomyelitis in lower end of femur (osteomyelitis was 1) Healed after several months. Open reduction, anterior approach	Fair. Reduction complete. Marked extra-articular changes developed in hip with limited motion and pain on severe. Observed year
2 M	7 1/2	Posterior (scapular) Left side	None	Pre-operative skeletal traction very effective. Open reduction, anterior approach	Fair. Reduction complete. Sciatic nerve injured during arthroscopy. Hip not tampered. Hip analyzed in good position with satisfactory weight bearing. Observed 4 years
21 M	5 mos	Posterior (scapular) Left side	Healed chip fracture of posterior acromion and top of great trochanter	Pre-operative skeletal traction very effective. Open reduction, anterior approach	Excellent. Reduction complete. Motion was 80 per cent normal after one year. Function very good. No pain. Observed 3 1/2 years
21 M	3 mos	Posterior (high dorsal) Right side	Healed chip fracture of posterior acromion	Pre-operative skeletal traction very effective. Open reduction, anterior approach	Excellent. Reduction complete. Motion was 81 per cent normal after 7 months. Function very good. No pain

minimus and medius muscles. This exposed the entire region of the acetabulum and showed it to be filled with dense tissue across which stretched the scarred tendinous mass of the iliopectineus muscle. The mass of scar tissue was dissected out piece by piece revealing intact cartilage within the acetabulum. After the head and neck of the femur were freed from the adjacent scar tissue an attempt was made to reduce the dislocation. This failed despite the fact that great force was used in pulling down the leg and manipulating it. Further attempts also failed until finally with the help of a large steel skull, reduction was completed. During the latter procedure a portion of the head of the femur was bruised and the cartilage torn off despite all efforts to prevent injury. The wound was closed in the usual manner and the leg was placed in a splint in a position of 30 degrees abduction.

Following this operation the patient's temperature varied from 38 to 40 degrees centigrade. Five days later the wound was reopened because of obvious secondary infection. A staphylococcus osteomyelitis of the hip followed and two incisions were necessary for drainage. The infection was rather severe and was followed by extensive destruction of the acetabulum and of the head of the femur. Roentgenograms taken 6 months later showed definite bony ankylosis of the hip (Fig. 7). The patient was able to walk satisfactorily. The patient was under observation for 3 years, during which time he suffered from several attacks of pain associated with renewed drainage from the hip.

OPERATIVE INJURY TO THE SCIATIC NERVE

CASE 3. A Chinese male aged 18 years, was first seen on April 3, 1920. The entrance examination revealed a posterior dislocation of the left hip which was the result of a fall 4 years previously. Roentgenograms showed that the head of the femur was lying on the ilium in the region of the greater sacrotatic notch. The upper portion of the head appeared somewhat flattened and osteoporotic as a result of the old injury. The general physical examination was essentially negative except for the condition of the hip.

On April 9, 1920, traction was started by means of a Steinmann pin inserted through the lower end of the femur. The weights were gradually increased up to 15 pounds and traction was continued for 5 weeks. At the end of this time roentgenograms showed that the head of the femur had been pulled down to the level of the acetabulum. Its anterior surface resting against the posterior margin of the socket. On May 17, 1920, open arthrotomy was performed. Ether anesthesia was used and a Smith Petersen incision was made. Exploration showed that the acetabulum was filled with dense fibrous tissue. This mass of tissue was removed exposing the intact cartilage. The secondary capsule was opened anteriorly and upon external rotation a portion of the head could be seen. The upper end of the shaft and the neck were held securely to the pelvis posterior to the acetabulum. When the fibrous bands were cut through, a branch of the superior gluteal artery was severed. Considerable hemorrhage followed and while we were working in a rather bloody field the sciatic nerve was divided. Apparently the nerve had been fastened to the posterior surface of the secondary capsule. Following the hemorrhage the patient showed a weak pulse and in the hurried dissection which followed, repair of the sciatic nerve was not performed. The head of the femur was completely reduced. A transfusion of blood was given immediately after the operation and the patient returned to the ward in satisfactory condition.

Two weeks later repair of the sciatic nerve was attempted but the proximal portion had retracted into the pelvis so

that end-to-end anastomosis was impossible. The hip was immobilized and 4 months later fibrous ankylosis was almost complete. Observations 1 and 2 years later showed that the hip was ankylosed in good position. The patient walked satisfactorily with the aid of a loupdrop brace.

A FRACTURE CAUSED BY LATE MANIPULATION

CASE 4. A Chinese male aged 36 years was first seen on July 1, 1925. Four and one half months previously he had been thrown from a wagon in such a manner as to dislocate his right hip. The general history and physical examination revealed nothing of importance. The results of routine laboratory tests of the blood and urine were normal. Local examination showed the right lower extremity to be in a position of 40 degrees abduction, 45 degrees external rotation and 45 degrees flexion with actual lengthening to the extent of 3 centimeters. Roentgenographic examination revealed that the head of the femur was totally displaced through the posterior part of the obturator foramen (Fig. 8A). A layer of dense bony material covered most of the surface of the dislocated head. This appeared to be calcified ligamentous and periosal tissue. The inferior rim of the acetabulum was fractured but the femoral head seemed intact except for a moderate amount of osteoporosis.

On July 30 closed reduction was performed with the patient under ether anesthesia. During the manipulations which were necessarily very severe and prolonged (1 hour) a cracking sound was heard. Following this the head of the femur slipped into the region of the acetabulum. A splint was applied and the patient returned to the ward in good condition. Roentgenograms taken immediately after the manipulation showed that reduction was quite satisfactory but at the expense of a fracture through the head. Several broken fragments of the femoral head remained in the obturator foramen (Fig. 8B).

Following the trauma of reduction a large hematoma developed in the right groin and for 8 days the patient ran a fever varying from 38 to 39 degrees centigrade. Two weeks after reduction a course in baking massage and active and passive motion was instituted. Two months later the patient walked upon the right leg but still complained of pain. He then had about 60 degrees of flexion but motion in other directions was greatly limited. In a follow up letter one year later the patient stated that the hip was painful upon bearing weight but nevertheless was greatly improved when compared to the previous condition.

LATE ARTHRITIS FOLLOWING OPEN REDUCTION

CASE 5. A Chinese male aged 28 years, was admitted to the hospital on August 23, 1926. The patient stated that 12 months previously he had fallen from a tree injuring severely the right hip. The entrance examination was essentially normal except for the right hip which was carried in the usual position of posterior dislocation. Roentgenograms showed the head of the femur lying on the posterior surface of the ilium in the region of the great sacrotatic notch (Fig. 9A).

Traction by means of adhesive tape was maintained for 21 days, but had little effect on the measurement of the distance between the anterosuperior spine and the internal malleolus. On September 3, 1926 open reduction was performed. Ether anesthesia was used and a Smith Petersen incision made. Following deep dissection, a triangular flap of skin, fascia, muscle and periosteum was retracted from the blade of the ilium. Subperiosteal dissection gave very satisfactory exposure of the acetabulum and the dislocated head of the femur. The acetabulum was filled entirely with fibrous tissue the removal of which required force and sharp dissection. Intact surfaces of cartilage were found.

When the secondary capsule was opened the head of the femur was found in the region of the greater sciatic notch. The cartilaginous surface of the head was intact except in one small area where it appeared thinned and flattened as though the underlying bone had been crushed. The tendinous fibers of the obturator internus and pyramidalis muscles lay in a mass of scar tissue which firmly held the base of the neck of the femur to the posterior margin of the acetabulum. These two tendons had been wound around the neck as they passed on to their insertions into the region of the great trochanter. After the upper end of the femur was released by sharp dissection, reduction was obtained by manipulation and traction. A long leg hip spica cast was applied and the patient had an uneventful convalescence.

Following 3 months of physiotherapeutic treatments, the functional result was excellent, with almost 75 per cent of the normal range of motion. On November 3, 1930 (3 years after operation) the patient returned for follow-up examination. The only complaint was slight pain after long periods of walking. Roentgenograms taken at that time showed that a large amount of new bone had developed around the head and neck of the femur (Fig. 9B). It was very surprising to find excellent function existing in the presence of such marked osteo-arthritis changes.

POSTERIOR DISLOCATION OF THE HIP CAUSED BY THE TRAUMA OF A RIFLE BULLET

CASE 6. A Chinese male, aged 34 years, was first seen on June 30, 1930, for an old gunshot injury (80 days) in the region of the left hip with retained foreign body. The wound had healed spontaneously a week after injury. The general physical examination was normal except for the condition of the hip. The laboratory examinations revealed no abnormal findings. The left thigh was held in a position of flexion (35 degrees), adduction (30 degrees) and lateral rotation, and the greater trochanter was 4 centimeters above Nélaton line. Roentgenographic examination of the hip confirmed the impression of posterior dislocation. It also showed a fracture of the head of the femur along with a fracture of the superior rim of the acetabulum (Fig. 9A). The foreign body was seen in the region of the left obturator foramen. There was no evidence of any infectious process in the hip.

On June 3, 1930, a Steinmann pin was inserted through the lower end of the femur and preliminary traction was started. Seven days later on July 1, 1930, the leg had been pulled down to its normal level (Fig. 10A). Three days later an open arthrotomy was performed through Smith-Petersen incision. All the scar tissue was cleaned out of the acetabulum. Upon opening the capsule, the head of the femur was seen to be fragmented in the inferior portion—changes suggesting the gradual absorption seen in aseptic necrosis (Johansen, Pfenister). Cultures taken from the head showed no growth. The dislocation was easily reduced by manipulation. The wound was closed in the usual manner and a plaster hip spica was applied with the thigh in position of 30 degrees abduction. The patient had an uneventful convalescence and was discharged in a cast 33 days after operation. One month later the cast was removed and physiotherapy was started. Roentgenographic examination at that time showed an increased amount of absorption of the injured area of the head and acetabulum

(Fig. 10C). Three months later the patient walked satisfactorily. The hip had undergone almost complete fibrous ankylosis. One year and 3 months following the operation the patient reported that he was able to work 7 hours daily. His only complaint was slight pain in the hip upon overuse.

SUMMARY

1. A review and discussion of the reconstructive surgery of old traumatic dislocations of the hip is presented.

2. Sixteen cases of old traumatic dislocation of the hip (15 posterior, 1 anterior) are reported. Three cases of 21 to 31 days' duration were reduced by closed manipulation after the method of Bigelow. One case of obturator dislocation of 4½ months' duration was reduced by the closed method at the expense of fracture of the head of the femur. By open arthrotomy complete reduction was accomplished in the 12 remaining cases.

3. The use of skeletal traction preliminary to open arthrotomy is emphasized.

Acknowledgment is due to Drs. C. W. Van Gorder, A. S. Taylor, J. P. Webster and L. C. Chu, whose cases are included in this study.

A TYPE OF PELVIS INTIMATELY ASSOCIATED WITH OCCIPITO-POSTERIOR POSITION

HERBERT THOM, M.D., F.A.C.S., NEW HAVEN, CONNECTICUT
From the Department of Obstetrics and Gynecology, Yale University School of Medicine

IN speaking of the differences in the configuration of the human pelvis William Turner in 1886 wrote 'with the exception of the skull no portion of the skeleton presents greater individual variations than the pelvis. These variations may have a profound effect upon the course and character of labor as is well known to obstetricians, and the pronounced types of contracted pelvis are well known and readily recognized. On the other hand there are many slight or moderate variations from the normal which remain unrecognized.'

In the present paper I wish to speak of pelvis in this latter group especially those characterized by a moderate or pronounced shortening of the transverse diameter of the superior strait often in association with abnormal lengthening of the anteroposterior diameter. I am convinced that this type of pelvis occurs with relative frequency, and that it has a distinct influence upon the course of labor, two facts that have not been sufficiently emphasized. My conclusions are drawn from a radiological study of pelvis now extending over twelve years. This experience has proved to me what I have on numerous occasions emphasized, namely, that the usual methods of external pelvimetry do not offer an accurate picture of the superior strait and at best can be considered only as guideposts to the true dimensions of this plane of the pelvis. It is therefore not surprising that moderate or even pronounced shortening of the transverse diameter of the superior strait should escape recognition for until the advent of roentgen methods there was no accurate diagnostic procedure available for pelvic mensuration of the superior strait.

It is an interesting historical fact that the plate depicting the pelvis in the great work of Vesalius shows the sacrum with six instead of five segments, so also does Deventer's, *New Light for Midwives* 1725. Sacral bones containing six segments are definitely associated with transverse shortening of the superior strait so that these plates do not depict what the authors undoubtedly intended, namely the normal pelvis.

In all mammals except man the transverse diameter of the superior strait is shorter than the anteroposterior. This relationship is known as the dolichopelvic pelvis in contrast to the platy-

pelvic pelvis in which the obverse obtains, namely the transverse is longer than the anteroposterior diameter. The platypelvic pelvis is characteristic of the human species. The dolichopelvic pelvis obtains throughout in the anthropoid apes and Turner states that when it occurs in humans there exists an 'animalized' arrangement.

In the pelvis of the newborn child the superior strait is narrower than in the adult, the ratio of the anteroposterior to the transverse diameter being 100:105 instead of 100:122.5 as in the latter. Fehling first pointed out that differences in form and appearance of the male and female pelvis are noted as early as the third month of fetal life and Thompson noted at this period differences similar to those of the adult. In his series the male index was 86 as against the female index of 83.

$$\text{Pelvic Index} = \frac{\text{Conjugate diameter} \times 100}{\text{Transverse diameter}}$$

When we study the essential differences of the adult male and female pelvis, we find among other characteristics that the transverse diameter of the superior strait in the male is shorter than that of the female, thus giving this plane in the former a more rounded appearance.

Berry Hart states that the ultimate shape of the pelvis is due mainly to a type growth before birth and not wholly to postnatal mechanical influences. He concludes nevertheless that the lumbar curve, the greater curve of the sacrum and the inclination of the pelvic brim to the horizon are all due to postnatal influences. He has thus classified the more common pelvic variations in this interesting manner:

Congenital which include

- 1 Normal female
- 2 Inverted pelvis (i.e., male type)
- 3 Justominor
- 4 Naegele
- 5 Robert
- 6 Achondroplastic
- 7 Infantile
- 8 Funnel
- 9 Assimilation

Postnatal which include

- 1 Flat
- 2 Flat rachitic
- 3 Scoliorachitic

Fig 1 Roentgenogram of pelvis showing unilateral high assimilation Anteroposterior diameter o centimeters transverse diameter o centimeters

In the above classification the inverted or male type pelvis is of unusual interest to us because its characteristics are

- 1 Smaller ilium
- 2 Smaller sacrum
- 3 Male type sacrosciatic notch
- 4 Symmetry of pelvis
- 5 Narrowing of transverse of brim

Nearly every textbook of obstetrics mentions the occurrence of the male type of pelvis in the female. When we consider that the essential difference from an obstetrical viewpoint is a decrease in the transverse diameter of the superior strait and of the outlet it is reasonable to suspect that these changes may exert a definite influence on labor. In a recent paper by Cornell on "The Conduct of Labor in the Dyatocia Dystrophus Syndrome Patient" although no specific attention was given to the exact type of pelvis present in the series (that is no outlet or X-ray measurements are mentioned) the description of the heaviness of the pelvic bones, the *relative increase in the external conjugate diameter* and the frequent occurrence of occiput posterior position leads me to the conclusion that shortening of the transverse diameter of the superior strait is probably also present in this type of patient.

Shortening of the transverse diameter of the superior strait is also characteristic of the high assimilation pelvis. It will be recalled that in this variation the transverse processes of the last lumbar vertebra fuse with those of the first sacral. By this process the last lumbar becomes the first sacral vertebra, the sacrum then being composed of six instead of five segments.

Occasionally in high assimilation one side of the last lumbar vertebra undergoes this fusing

TABLE I—SUMMARY OF FIGURES

Curve	Anteroposterior diameter cm	Difference	Transverse diameter cm	Course of labor
	8	+ 75 =	75	L O P breech
	75	+ 5 =		R O P primary
2	8.5	- 25 =	3.5	R O P persistent
	5	+ 5 =		R O P primary
3	4	- =	3	R O P persistent, breech
4		+ 75 =	75	R O P persistent, breech
7		+ 75 =	75	L O P primary
8		- =		R O P persistent, breech
9	75	+ 5 =	75	R O T low transverse or arrest, breech
	12.75	- 5 =	5	R O P persistent, breech
		- =		R O P primary
		- 5 =		R O P primary
5	5	- 75 =	5	R O P primary
	5	- 5 =		R O T small baby (joe grams)
6		+ 5 =		L O T low transverse or arrest, breech
10	75	=	22.75	R O P primary
7	75	+ 5 =	22	R O P primary breech from R O T
8	10	+ 5 =		L O P persistent, breech
9		+ 50 =	5	R O P persistent, breech
10	3.5	- 50 =	75	R O P primary

process while the other side does not, as is shown in the accompanying roentgenogram (Fig 1). In Paterson's study of 265 dried pelves this unilateral assimilation occurred in 18 or 6.79 per cent, while 61 or 23 per cent, showed the presence of more than five sacral vertebrae. Emmons, in an analysis of 317 Indian squaw pelves, found the incidence of assimilation to be 21.7 per cent.

From these studies we conclude that high assimilation is of relative frequency and is definitely associated with shortening of the transverse diameter of the superior strait. Indeed occasionally this variation of the pelvis gives rise to a dolichopelvic pelvis.

One of the most interesting clinical reports on this subject is that of Fabre and Trillat in 1920. They record the results of a radiographic study of 12 pelves which they designate as "Pelvis with anteroposterior diameter predominating." In all of their series the fifth lumbar vertebra was sacralized, i.e. high assimilation was present. In seven of these, delivery occurred with the occiput posterior. Fabre and Trillat conclude "for us this has the relation of cause and effect and

Fig. 2. Roentgenogram of pelvis (dolichopellic type). Anteroposterior diameter 13.0 centimeters transverse diameter 11.0 centimeters.

Fig. 3. Roentgenogram of pelvis (dolichopellic type). Justomajor external measurements anteroposterior diameter 13.0 centimeters transverse diameter 12.5 centimeters.

we believe that this special form of the superior strait which we have shown in radiographic measurements and to which we have applied the name pelvis with anteroposterior diameter predominating is the principal cause of births in the occipitoposterior position.

I am convinced that not only are such pelvises as these authors describe associated with occipitoposterior position but that lesser degrees of transverse contraction whether due to assimilation, male type of pelvis or to unnamed causes are definitely associated with both primary and persistent occipitoposterior position. I am also of the opinion that many pelvises which from their external measurements are classified as generally contracted are contracted only or chiefly in the transverse diameter of the superior strait. These are the so called small round pelvises. In many of these the diagonal conjugate diameter is within the limits of normal.

During the past year in connection with our roentgen pelvimetry and cephalometry studies I have been impressed with the frequency of the occurrence of pelvises in which the chief deviation from normal is a relative or real decrease in the transverse diameter of the superior strait. Twenty such pelvises have been studied particularly in reference to the course of labor.

The first 16 of this series have been reported in detail in another publication. An important point in this study is the fact that the series represents 20 consecutive cases of this type and that every one was associated with primary or with persistent occipitoposterior position.

A summary of the figures obtained from our study is shown in Table I.

The diagnosis of position in all instances was made by vaginal examination during labor. Those cases which are designated as primary posterior position subsequently delivered with the occiput anterior while in 2 cases which were delivered by forceps from low transverse arrest I assume the occiput entered the pelvis in the posterior position. In only 2 instances did the transverse diameter of the superior strait exceed the anteroposterior diameter by as much as 1.0 centimeter (normal 2.5) while in one instance in a patient with justomajor external measurement the transverse diameter was actually less by 2.5 centimeters than the anteroposterior diameter a true dolichopellic pelvis.

I regret that in this group I cannot report upon the incidence of high assimilation. In order to determine accurately the presence of this entity either lateral or direct anteroposterior pelvigrams should be taken. In the system of roentgen pelvimetry which we employ it is not possible in the developed film to count the sacral segments. Nevertheless in one case of outspoken transverse diameter shortening a lateral pelvigram showed only the usual number of sacral vertebrae. My belief is that shortening of the transverse diameter of the superior strait does occur frequently in the absence of high assimilation or other outspoken pelvic anomaly.

In reviewing our findings, I am mindful of a sentence from the writings of Sir Oliver Lodge which reads 'always we must be guided by experience and be loyal to facts whether we understand them or not.' The facts stated are cer-

Fig. 4. Normal pelvis, solid line; composite pelvis, dotted line.

tainly interesting and certainly not easy of complete understanding. When one surveys statistics dealing with the incidence of posterior presentations, he becomes involved in a maelstrom of figures which are largely meaningless. Thus Pinard gives an incidence of 38.8 per cent while Williams, in a large series, reports 11.68 per cent. The latter writer, however, states that the incidence is probably twice this figure. I think that 20 per cent for primary occipitoposterior positions probably represents a figure somewhere near the truth. It is, of course, an interesting speculation as to the real cause of the high incidence of occipitoposterior position in the series here presented. My own interpretation of the facts may be stated briefly. If we consider 11 centimeters for the normal conjugata vera and 13 centimeters for the normal transverse of the inlet, and apply them to the figures for these diameters in the above series we see two interesting facts. First, in 17 of the 20 cases the transverse diameter is less than the normal figure, and in 14 of the series the anteroposterior diameter actually exceeds the normal figure. The average figures are transverse diameter 13.1 centimeters less than the normal, conjugata vera 1.75 centimeters more than normal. If we visualize these figures in the accompanying diagram (Fig. 4), the solid line representing the normal pelvis and the dotted line representing a composite pelvis based on the figures mentioned. I think we can agree that the occiput would assume a primary posterior position much more readily in the latter than in the former. I am well aware that other factors may

enter into the cause of occipitoposterior position. When one reads the amazing list of suggested causes in modern textbooks the aggregate is most bewildering. However I am convinced that the shape of the pelvis and particularly the type of pelvis present in this series, is a most potent factor in the production of primary occipitoposterior position. In reducing this type of pelvis to an entity in which the chief variations seem to be a prolongation of the anteroposterior diameter in combination with a moderate shortening of the transverse diameter it may appear like putting the cart before the horse to call it a transversely contracted pelvis perhaps the elongated anteroposterior pelvis is more descriptive.

I summarize my impressions as follows:

1. The type of pelvis described here is far more common than heretofore appreciated.
2. The extraordinary incidence of primary and secondary occipitoposterior positions noted indicate that this type of pelvis is a most potent factor in the production of this position.
3. Unless we make an accurate survey of the pelvis of every primiparous patient we are not doing our whole duty to the patient or practicing modern scientific obstetrics.
4. At the present time an accurate survey of the superior strait in the living subject can only be secured by roentgen pelvimetry.

ROENTGEN MEASUREMENTS IN PREGNANCY

A FEW PRACTICAL METHODS AND A SIMPLIFIED PROCEDURE USED BY THE AUTHOR

GEORGE E. MOORE, B.S. MD. ANTIGO, WISCONSIN

THE taking of pelvic measurements in obstetrics in some manner or another is nearly as old as the subject of obstetrics itself. As the study of pelvimetry as a diagnostic procedure advanced, it was found and generally conceded that external pelvic measurements were not indicative of the size of the inner pelvis as they were formerly thought to be and it was therefore concluded that the only pelvic measurements of any value were those obtained by taking internal measurements. For this latter type of procedure many methods and many instruments were devised. In some hands this procedure seemed to have considerable value in obtaining the desired information regarding the size and shape of the inner pelvis. The chief objections however have been mainly the distress it causes most patients and the lack of ability in the hands of many to obtain what could be called accurate results.

To know the exact size and shape of the true pelvic inlet is admitted by all to be of extreme diagnostic value in any obstetrical procedure. It is also true that the size and shape of the superior pelvic strait is more important than is that of any other pelvic region due chiefly to the fact that this location is most subject to variation in any disease of the bones of the pelvis.

The false pelvis which is formed by the flaring of the iliac bones above the opening of the true pelvis is of very little importance in the conduct of labor. During pregnancy it gives some support to the fetus and is instrumental in directing the head of the child into the true pelvis just prior to or at the time of labor.

The true pelvis itself is an elongated curved canal composed of bony, fibrous, and muscular tissue. This canal is also made up of three anatomical regions, the entrance or inlet, the canal proper and the outlet. It is the entrance of this true pelvis that we are particularly interested in for the reason stated.

While it must be admitted that many other things enter into the successful conduct of labor, such as the strength of the uterine muscle, the relaxation of the iliopectineal muscles and the other soft tissues, the condition of the placenta, kidneys, her heart and her general mental and physical makeup, nevertheless, the size and shape of the pelvic inlet remain as a diagnostic element of ex-

treme importance. As the size of the child's head is fairly constant and not subject to much variation, the size and shape of the inlet is considered the most important.

In contrast to the waning methods of internal pelvimetry by manual and instrumental means, we now have the gradual advancement of the more popular procedure of roentgen pelvimetry and its associated method cephalometry. The major part of this work, however, at the present time is still confined to the larger medical centers, their teaching hospitals and radiological laboratories, and it is no fault of the procedure that at the present time it is not more universally used. There are however, two conditions preventing this method from being more generally in vogue. One is a lack of knowledge of the procedure among many practitioners interested in obstetrics. The other is an opinion among many that the method involves extreme technicalities and can only be performed in highly specialized X-ray laboratories. This latter statement is not true and there are many physicians today, both in large and small communities, doing obstetrics who have their own X-ray laboratory or who have access to X-ray laboratories in the hospitals in which they work who could with very little effort make use of this valuable diagnostic procedure.

When we stop to consider that in this country alone upwards of twenty thousand women annually lose their lives from some complication of childbirth and that more than three times as many infants die at the time of birth, we will have to admit that the medical profession in this respect have a very fertile field of endeavor. And not only have we that to consider, but it is also true that upward of one half of the gynecological operations performed are with the idea of correcting some condition that had its inception at the time of childbirth. Good obstetrics like every other field of medicine and surgery is dependent upon good diagnosis.

The subject of roentgen pelvimetry as a diagnostic procedure in obstetrics is older than one would ordinarily imagine. The roentgen rays or X-rays, as they were called at the time, were discovered by Roentgen in the fall of 1895. Scarcely 2 years had elapsed when Budin published an article in which he brought out the fact that it was

Fig. 1. Pubic scales used by Rowden

more important to know the shape and circumference of the superior pelvic strait than that of the anteroposterior diameter. This article was based on the findings of a roentgenogram of a deformed pelvis.

This same year 1897 Varner wrote his first article entitled *Pelvigraphie et pelvimetrie par les rayons x* (Pelvic photographs and pelvic measurements by the use of X-rays). In this article he states that in the year 1896 in conjunction with other collaborators, work was begun on roentgen pelvimetry. The first roentgenograms were taken on the body of a woman who had died of intestinal obstruction 9 days following confinement. He also found that, due to the limited capacity of their X-ray equipment it was very difficult to get roentgenograms that were very distinct, especially in large women or women in the latter half of pregnancy. In conclusion he remarks that it is possible by the use of X-rays to diagnose pelvic conditions that could not be diagnosed by any other means.

Albert, in 1899, published a very classical article entitled *Ueber die Verwertung der Roentgenstrahlen in der Geburtshilfe* (The use of X-ray in gynecology). The author advocated the use of the semi-recumbent position in order to get the superior strait in a parallel position with the film. He also used the upper margin of the fifth lumbar vertebra and the superior part of the symphysis as his locations for placing the superior strait in this parallel position. His calculations were made by a mathematical procedure in which known quantities, distance of superior strait from film, and focal distance of the tube were used.

Fabre and Fouchert in this same year wrote of their first work and described what is now commonly known as the Fabre method. The work of Budin, Varner, Albert, and Fabre and Fouchert at this early stage seemed to establish roentgen pelvimetry as a definite procedure and was the foundation from which the later work received its incentive.

From then on until the present time the British, French, German, and American workers have pre-

Fig. 2. Roentgenogram of pelvis with scale attached as used by Rowden.

sented a succession of articles pertaining to this subject. These articles describe a variety of procedures and at the present time we have a great many valuable methods from which to choose.

Hirsch in the discussion of a paper by Thoms (38) in 1922 divided the various methods of roentgen pelvimetry into 5 types, comparative, teleroentgenographic, frame, triangulation, and stereoroentgenographic methods. The classification is very complete and covers the entire field of roentgen pelvimetry from its inception.

1. *Comparative*. Radiograms taken of dried pelvis. These are compared with radiograms of pelvis of living individuals. A matching of radiograms, so to speak, and the referring back to the original dried pelvis for measurements.

2. *Teleroentgenographic*. By establishing a long focal film distance with the superior strait of the pelvis parallel to the film, distortion is reduced to a minimum.

3. *Frame*. By this method a scale is superimposed at the same level at which the measurements are to be taken and when an exposure is made, the scale superimposed on the film, is distorted in the same proportion as the region to be measured. Measurements are then read directly on the film from the distorted scale.

4. *Triangulation*. A study of triangles with known quantities, the procedure involving the same principles of mathematics and radiology as used for the localization of foreign bodies.

5. *Stereoroentgenographic*. Patient is first placed in such a position that the obstetrical land-

Fig. 3. Distorted centimeter graph as used by Walton

marks to be used will best be seen on the film. Stereoscopic roentgenograms are taken with a known tube shift and a known focal distance. The film center must be known in relation to the focal point and the shift of the tube must be parallel to the film. Computations must be made by the use of precalculated tables and formulas or by means of mechanical devices used to reconstruct the problem involved.

I have classified the procedures according to the recognized methods in vogue today. They are as follows: (1) methods based on mathematical calculations alone; (2) methods based on mathematical calculations associated with triangulation and stereoroentgenographic procedures; (3) scale methods.

The two latter types are the ones most commonly used today.

The past 2 or 3 years seem to have divided the workers in roentgen pelvimetry into two schools. The one class striving for extreme accuracy but involving technical methods beyond the scope of the average physician but methods well adapted to technical laboratories or in teaching hospitals; on the other hand a group of workers striving for practical methods easily performed and entailing the least amount of technical procedure but still

Fig. 4. Type of pelvimeter used by author. Somewhat similar in appearance to that of Thoms.

maintaining enough accuracy for all practical purposes.

There is no doubt but that each group has excellent reasons for the methods advanced but it is also true that if roentgen pelvimetry is to be a thing of real worth it will have to be of such a nature that it can be used and understood by the great majority of physicians doing obstetrics throughout this land. It will have to be practiced in the regions where twenty thousand women are annually losing their lives from complications of childbirth.

From a roentgenological standpoint every primipara and every woman who gives a history of difficult labor when reporting to her physician and the diagnosis of pregnancy has been made should have a roentgenogram taken to determine the dimensions and shape of the pelvic inlet. If it is found at this time that the patient has a small or distorted pelvic inlet the regular routines of diet and general care that are usually used can be followed out. Just prior to labor a roentgenogram can be taken to determine any evidence of distortion and if such is manifest the physician can resort to cephalometry.

Every case whether primipara or multipara should have a roentgenogram taken at approximate term to determine and diagnose the position of the child, the probability of multiple pregnancy, the possibility of malformed fetus and the possibility of disproportion between the pelvic inlet and the head of the child. If there is any evidence of disproportion cephalometry can be resorted to. If any other abnormal condition is found the physician can then plot his course as regards each individual case.

If that type of procedure along with the better present day methods of prenatal care is adopted and adhered to a few years should show some results. The more prenatal care the less natal and postnatal trouble.

Fig. 4. Type of scale superimposed on film by pelvimeter as used by Thoms. Pelvic measurements are made by counting spaces made by dots between points to be measured.

is located and a mark placed on the mother's abdomen at a point above the center of the child's head. A mark is also placed on the lateral abdominal wall opposite the center of the child's head. The distance of the center of the child's head from the film in the plane at which the measurements are to be taken must be known.

The first exposure is made above the center of the child's head at a thirty inch focal film distance. The second exposure is made lateral over the lateral mark on the mother's abdomen at a focal film distance of thirty inches. The fronto-occipital and biparietal diameters are measured with calipers on the film and the corrected measurements are made on the chart.

METHOD OF THOMS

Thoms (32, 33) of New Haven, Connecticut has done a large amount of work on roentgen pelvimetry over a period of some years. His contributions to the subject have been many, and throughout the course of his work he has always adhered to procedures which have been practical and which are classified as scale methods. The scale he has been using for the last few years consists of a lead plate the entire surface of which is perforated with small holes (Fig. 5). These holes are placed at the intersection of lines running horizontal and vertical which are 1 centimeter from

Fig. 5. Type of scale superimposed on film by pelvimeter designed by author. Note the small dots.

each other. When this scale is reproduced on the film it causes the film to be covered with small dots which are an equal distance apart and the spaces between which are distorted in proportion to the distance that the scale is removed from the film.

The procedure of Thoms is as follows: A small piece of adhesive is placed over the spine at the region of the junction of the fourth and fifth lumbar vertebrae. The patient is placed over the film in a semi-recumbent position. In the work of Thoms, I see no mention of him using a Bucky diaphragm and it is my opinion that he uses none. The tube is centered over the pelvis about 5 centimeters posterior to the symphysis. A plumb line is dropped from the frame of the tube holder to the top of a symphysis and this gives the location of that region. The distance of the adhesive tab on the back to the film is measured with calipers. A straight line drawn through the adhesive tab and the tip of the plumb line passes through the plane of the pelvic inlet.

An exposure is now made and the patient is then removed from the table. The lead scale is then placed in the plane of the pelvic strait which previously was located by the height of the adhesive tab from the film and the tip of the plumb line. A short exposure is now made which imprints the scale (Fig. 8) on the film. It is not necessary for the pelvic strait to be parallel with the film in this procedure but for accuracy in lo-

Fig. 10 Flexible ruler with centimeter scale used for making measurements by author's method

ating the sacral promontory it should be nearly so. The corrected measurements are made by reading the number of spaces between dots connecting the points desired to be measured. This gives the various diameters directly in centimeters.

The procedure for cephalometry is similar the scale being superimposed in the same plane as the region of the head to be measured.

The method is very practical and logical. There is nothing in the procedure but what can be duplicated by a physician or radiologist with average equipment and average ability.

METHOD OF AUTHOR

In the method I have just recently devised and which I am using at the present time the procedure is similar to that of Thoms in that a sheet lead scale is superimposed in the plane of the pelvic strait. The variation comes however in the type of scale used and the method of making the measurements. The procedure is as follows:

A point on the spine at the upper border of the fifth lumbar vertebra which point was referred to by Albert in 1899 is located and a small piece of adhesive placed over this region. A line drawn from that point through the superior border of the symphysis pubis passes through the plane of the inlet of the pelvis. This method of locating the plane of the superior strait was described by Albert in his first article written in 1899 and has been used ever since by all workers whose methods have necessitated the locating of the plane of the superior strait.

The patient is placed in a semi-recumbent position (Fig. 7) with the pelvis centered over the cross lines on the surface of the Bucky diaphragm. By the use of calipers the distance from the adhesive tab to the Bucky is determined. By using a ruler the distance from the superior surface of the symphysis to the Bucky is measured. The patient is adjusted so that these two measurements correspond. This places the plane of the inlet in a position parallel to the film. For the correct location of the lower border of the superior point of the symphysis and the correct location of the sacral promontory. It is my opinion that this

Fig. 11 Flexible ruler extended, showing distorted scale. Each centimeter distorted an equal and proportionate amount.

is the correct position. Where the strait of the pelvis is not placed parallel to the film I believe that for the correct location of the sacral promontory stereoscopic films should be taken.

The tube is now centered to correspond with the cross lines of the Bucky at a focal film distance of 30 inches. An exposure is made of the pelvis. The patient is then removed from the table and the lead scale placed in the same plane as the pelvic inlet. This is accomplished by using the measurements previously mentioned and with the Bucky running a short exposure is now made which superimposes the scale on the film.

If the patient is one with known deformed, generally contracted or just minor pelvis or if one wishes to vary the technique by not having the plane of the pelvis parallel to the film the procedure then varies and stereoscopic roentgenograms are taken of the pelvis instead of a flat film. The scale in this latter instance is superimposed on one of the stereoscopic films. The reason for adopting this method is that the stereoscopic roentgenograms gives one a better visualization of the pelvic inlet, makes the parts desired to be measured more distinct and gives one a better localization of these points. This is a considerable help in cases as already mentioned.

The pelvimeter consists of a lead sheet approximately 16 by 19 inches in size. This sheet of lead is 1/16 of an inch thick and held firmly to a board of the same dimensions by screws placed around the border of the lead plate. The board is approximately 3/8 inch thick and made of basswood. Stiles are placed across each end of the board to prevent warping. Legs are mounted on the board and by the use of thumb screws the pelvimeter can be lowered or raised (Fig. 4).

On the surface of the lead sheet a line running in the longitudinal center of the plate intersects a transverse line at right angles at the center of the plate. By the use of a small sewing needle two holes ten centimeters apart were made in the former line and equidistant from the intersection with the latter line (Fig. 6). When an exposure of this scale is made on the film two small dots in the

region of the pelvic inlet are reproduced on the film (Fig 9).

In an article recently published Moore and Skinner proved that when a perforated lead plate such as Thoms uses is placed between the focal point of an X-ray tube and a film, with the position of the lead plate parallel to the film, the space between the dots reproduced on the film when an exposure is made will all be equally distorted and the space between the dots would be the same whether near the center of the film or near the periphery. Therefore the space between two dots 1 centimeter apart is distorted on the film the same amount regardless of where they appear on the film. Also the space between any two points 10 centimeters apart on the scale would be distorted on the film a proportionate and equal amount to all dots on a scale 10 centimeters apart. Then each centimeter of the 10 centimeter scale would be distorted an equal amount and would not necessarily have to be represented by a dot on the film. Therefore the two dots on the film represent the proportionate distortion for all measurements made on that particular film.

To complete the procedure then and make the measurements, it is only necessary to have a ruler that can be distorted in the same proportion that the two dots on the film are distorted. This has been accomplished by making a ruler out of flexible and uniform rubber. A normal centimeter scale 10 centimeters long is printed on the rubber ruler. A frame is constructed to hold firmly the rubber ruler, one end of which is movable and can be extended to any desired distance and held in position by a thumb screw (Fig 10).

When it is desired to take measurements of the pelvic inlet on a certain film all that is necessary is to extend the ruler until the zero mark and the 10 centimeter mark are the same distance apart as the two dots on the film. Then one has an equally distorted ruler on which each centimeter is distorted an equal amount and the pelvic measurements can be made directly on the film as one would make measurements with a ruler (Fig 11).

The value of this procedure is in its simplicity as well as its accuracy. The fact that only two dots are necessary makes the construction of the pelvimeter very accurate and easy. The making of the pelvic measurements on the X-ray films by the use of a ruler is certainly simplicity itself. In cephalometry the scale is superimposed in the same plane as the region of the head to be measured.

CONCLUSIONS

Accurate pelvimetry is a valuable diagnostic procedure in obstetrics.

Röntgen pelvimetry is gradually superseding manual and instrumental pelvimetry due chiefly to the fact that it is a much more accurate procedure.

There are many good methods of roentgen pelvimetry in use at the present time, many of which are simple and practical enough for the use of any obstetrician.

The value of roentgen pelvimetry as a diagnostic measure in obstetrics is dependent upon simple and practical methods in the hands of many rather than complicated procedures in the hands of a few.

Any good recognized method is accurate enough for all practical purposes.

Cephalometry is a valuable adjunct to pelvimetry in the study of disproportion in certain cases.

Recommended routine would be as follows:

1. Roentgen pelvimetry on all primiparae as soon as pregnancy is diagnosed.

2. Roentgen pelvimetry on all multiparae with history of difficult labors.

3. Routine care and diet by obstetrician in all cases where small pelvic inlets or distorted pelvis is found.

4. Roentgenogram of all obstetrical cases just prior to term.

5. If latter procedure shows any evidence of disproportion, cephalometry should be resorted to.

If this routine is adhered to there should be some manifest reduction in mortality in obstetrics.

INTRARENAL AND PERIRENAL LIPOMATA

JOHN DE J. PEMBERTON M.D. F.A.C.S. ROCHESTER MINNESOTA

Division of Surgery The Mayo Clinic

JOHN M. McCAUGHAN M.D. ROCHESTER, MINNESOTA

Fellow in Surgery The Mayo Foundation

LIPOMATA or fatty tissue tumors have well defined gross, microscopic and chemical characteristics. They are subject to secondary degenerative changes in advanced growth and are frequently found in combination with other connective tissues and are then classified as fibrolipomata myxolipomata, chondrolipomata and so forth. The lipomata are of clinical significance because (1) the larger lipomata produce serious pressure effects on adjacent structures (2) large lipomata have caused emaciation by diverting nutrition from the body (Wells) (3) multiple lipomata may occur a condition noted by Virchow in which hundreds of lipomata throughout the body are found in such organs as the lungs, liver and other tissues where fat normally is absent and (4) sarcomatous transformation may appear and recurrence after removal is not infrequent and is sometimes evidence of this malignant change.

The etiology of these growths is unknown but various hypotheses have been advanced to explain their origin. The general etiological classification of lipoma and lipomatoid processes of Ewing is as follows: (1) obesity (2) localized overgrowth of fat tissue as, for example, the so-called fatty neck or lipoma annulare colli (3) replacement lipomatosis, seen in atrophic organs, for example, the kidney and lymph nodes (4) homologous lipoma for example the solitary subcutaneous lipomata (5) heterologous lipoma for example intrarenal lipoma, and (6) overgrowth lipomata consisting of the mixed tumors and teratomata. Other conditions which have been suggested as possible etiological factors are hereditary influences, congenital predisposition, disturbances in thyroid and pituitary glands, alcoholism, trauma, inflammation.

Heterologous lipomata may arise in the kidney as stated by Alsberg from misplaced groups of embryonal tissue cells from the fat capsule, which become enclosed in the parenchyma of the kidney in the process of development. Warthin, on the other hand, stated his belief that fatty metamorphosis occurs and that the lipomata arise from the connective tissue of the kidney by transformation of fibroblasts into fat cells.

Grawitz pointed out the existence of true intrarenal lipoma. He believed that they were rare

and he emphasized the importance of distinguishing them from the larger group of renal neoplasms with high fat content but which microscopically simulated suprarenal tissue. To this latter group he applied the term hypernephroma.

Intrarenal lipomata differ from pararenal lipomata by taking origin from tissue in which fat normally is absent. In the literature two varieties of intrarenal lipomata have been described the most common are small circumscribed single or multiple either pure or mixed, and less common is the so-called replacement lipomatosis form noted by Askanazy. To our mind this type does not belong in the group of lipomata because it does not represent pure tumor but rather fatty replacement which in the kidney is associated with atrophy, infection and the formation of calculus. The same pathological process is observed in many other parenchymatous organs undergoing atrophic degenerative changes.

The perirenal lipomata take origin from the perinephric fat and contain as a rule more connective tissue. Areas with accumulation of mucinous fluid are often seen and sarcomatous change is not infrequent. Their growth, ordinarily slow, may progress rapidly with malignant change and recurrence after operative treatment is not unusual. As the perirenal lipoma advances in growth and attains large size, it encroaches on the peritoneal cavity by elevating the posterior parietal sheath, and is then classified simply as a retroperitoneal lipoma. The anatomical distinction from lipomata originating from adjacent adipose structures often being impossible.

REVIEW OF LITERATURE

The literature in general consists of single case reports or small series of cases. A few writers have published larger reviews of the subject. Von Wahlfendorff for example reviewed 165 cases of retroperitoneal lipoma of all types: 70 cases (46 per cent) were pure lipomata and 83 (54 per cent) were mixed. Of this latter group 32 (30 per cent) were fibrolipomata, 16 (10 per cent) myxolipomata, 15 (10 per cent) fibromyxolipomata, and in 21 (14 per cent) there was sarcomatous change.

Retroperitoneal lipoma occurred most commonly in the fourth decade, although one case was

Fig. 1 Specimen showing the cut surface

found in the first year of life and one in the eighth. One hundred six patients (72 per cent) were females and 42 (28 per cent) were males. In 132 cases in which the site was definitely recorded it was in the abdomen in 104 cases (79 per cent) and in the pelvis in 28 (21 per cent). From the pathologico-anatomical standpoint 30 cases (23 per cent) were limited to the capsule of the kidney and 46 cases (35 per cent) involved the perirenal and lumbar fat. In von Wahlen-dorf's opinion the myxoma represents a transitional form between benign and malignant.

Albarán and Imbert in a total of 54 retroperitoneal tumors, found 22 lipomata, 6 lipomyxomata, 12 fibromyxolipomata, 1 myxoma and 17 with sarcomatous change. Adami recorded 42 cases of lipoma of the retroperitoneal tissue in general, a third of them originated around the kidneys.

Le Fur cited 122 cases, 110 of which had been reviewed by Thevenot, and they overlap to some extent those reviewed by von Wahlen-dorf. The remainder were additional cases reviewed by him since the war. Lecene in 33 cases found an incidence of 70 per cent in females and 30 per cent in males. The average age was from 40 to 50 years, but there was 1 case in the first year and 1 in the seventh decade. The incidence of occurrence on both sides of the body was equal. Only in the smaller tumors could the point of origin be determined with any degree of certainty. In his series of 33 cases there were 6 lipomata, 4 fibrolipomata, 2 fibromyomata, 3 fibromyxomata, 5

fibrosarcomata, 2 angiosarcomata and two mixed tumors.

Flansky in a study of the so-called replacement lipomatous or renal atrophy with fat substitution found the total number of cases of perirenal lipomata reported in the literature as approximately 150. He quoted Lubarsch as saying that in the 40,000 necropsies at the Berlin Institute from 1897 to 1917 only one case of fatty tumor of the capsule of the kidney was seen.

Because of the rarity of this condition probably most of the cases encountered have been reported in literature, but in many instances the origin of the tumor, whether from the capsule of the kidney or from the perirenal fat, is not stated. Flansky's case of diffuse fatty replacement of renal tissue is similar to those reported by Dick-

Fig. 2 Specimen showing attachment to the kidney

Fig. 3. Specimen showing capsule of tumor and the adult adipose tissue, the structure of which the tumor was mainly composed (low power)

mson, Warthin and others. Rokitsansky and Alsberg stated their belief that the condition is primary, but the considerable degree of adhesions, the parenchymatous atrophy and the frequent association with renal calculi speak strongly in favor of an inflammatory basis. Warthin stated that most of the references to lipoma of the kidney found in the older literature do not deal with true lipoma, but with masses of fat surrounding an atrophied kidney, of which the dilated pelvis or ureter contained a calculus. Usually the kidney was completely surrounded by the tumor, hence the capsule was looked on as the origin of the growth. Crabtree stated that perirenal lipomata are more common than intrarenal, but this was not the experience of Hunt and Simon. The latter emphasized the point that perirenal

Fig. 4. Specimen showing an island of embryonic fat tissue (high power)

Fig. 5. Specimen showing intimate relation of base of tumor with renal cortex, complete absence of renal capsule may be noted (low power)

lipomata, if large, are likely to be of more clinical significance.

Smaller series of cases or reports of single cases of especial interest may be found in the papers of Barclay, Lacrampe, Esselsberg, Alsberg, Warthin, Reynolds and Wadsworth, Hirsch and Wells, Alexander, Samuels, Lower and Belcher and Crabtree.

Most writers agree that the diagnosis of these tumors is difficult. Symptoms are absent or obscure until the enlargement is sufficient to produce disturbance in adjacent organs by compression. Hence, delay in recognition is usual. The earliest symptoms noted in the literature, when the gastro-intestinal tract has been compressed have been primarily vague dyspepsia with dull pain in the back, heaviness after meals, vomiting

Fig. 6. Specimen showing the large blood vessels in the region of the renal cortex (low power)

diarrhea, constipation, and in some instances chronic or acute ileus. Pressure on the kidney of the pelvis and ureter have produced hydronephrosis, pyelitis, oliguria, or anuria. The more general symptoms noted were weakness, fatigue, nervousness, and inanition without definite cause. On the objective side, the discovery of an abdominal mass, occupying the retroperitoneal lumbar region is the most significant single observation. Whether such physical method as palpation, percussion, and insufflation of the large bowel can be depended on to define the situation of the lesion is open to question. Urological methods should always be invoked in order to implicate or exclude the genito-urinary tract. Exploratory laparotomy should be advised whenever such a tumor is suspected, as the condition is essentially surgical and the diagnosis is rarely made before operation. It is as de Quervain has said: *Jeder Regel spotten die Geschwulste der Nierenfettkapsel*.

The earliest case of retroperitoneal lipoma in which operation was performed was reported by Lizaris in 1824. The treatment is surgical and should be as early and as complete as possible. The choice of surgical approach depends chiefly on the size of the tumor; most authors prefer the lumbar route for the smaller tumors because of its lower mortality, and the abdominal route for the larger tumors because of the increased accessibility. Nephrectomy is indicated whenever the kidney is intimately adherent to the tumor. Nephrectomy was required in 138 operations (29), 29.7 per cent. Hartman and Leche performed nephrectomy in 18 of 27 cases and de Chamoff removed the kidney in 14 of 46 cases. Extirpation of the tumor by morcellation is occasionally the only means possible but should be avoided when possible because of the danger of spreading tumor cells of infection and of hemorrhage. Drainage usually is advocated because of the extensive raw surface left after ablation of large tumors.

In von Wahlendorf's series of 165 cases 113 came to operation. Twenty-nine patients died during or at the conclusion of the operation, a mortality of 25 per cent. Twenty-one (14 per cent) of the growths were sarcomatous, and 20 per cent of the remainder were considered borderline between benign and malignant. In 60 cases (54 per cent) cure was obtained. Nine patients could not be traced. Albarran and Imbert reported a mortality of 30 per cent in their 54 cases, and Thevenot, in his 110 cases a mortality of 23 per cent, whereas Le Fur, on adding his 12 cases to those of Thevenot, obtained the slightly higher figure of 25 per cent. Recurrence was fairly com-

mon. Von Wahlendorf noted recurrence in 15 cases, 14 per cent of his 113 operative cases. In 3 of Le Fur's cases there was recurrence, both local and general. In 2. In each instance in the latter the pathologist had made an unqualified diagnosis of benign lipoma. Consequently Le Fur prefers to consider all pararenal tumors as malignant and to extirpate as widely as possible in order to diminish the risk of recurrence.

From summarizing the literature we conclude (1) the etiology is unknown, (2) the condition is more common among women, (3) the diagnosis is difficult and before operation almost impossible, (4) the treatment is surgical, (5) the operative mortality is fairly high, and (6) malignant change and recurrence are fairly common.

REVIEW OF DATA CONCERNING CASES IN THE MAYO CLINIC

At The Mayo Clinic, Masson and Horgan reported 12 cases of retroperitoneal lipomata. Mayo and Dixon and Hunt and Simon reported 3 cases and 2 cases respectively.

We reviewed the 314 case records of retroperitoneal tumors observed in the clinic between the years 1910 and 1930 and in 42 of these retroperitoneal lipomata were recorded. Forty tumors were extrarenal and 2 were intrarenal. Nineteen patients were men and 23 were women. The youngest was aged 28 years and the oldest 68. The average age was 49.3 years. The average duration of symptoms was 5.8 years, the shortest being 3 weeks and the longest 20 years. A diagnosis of retroperitoneal tumor was suggested in only 5 cases. In 21 cases the pre-operative diagnosis was incorrect and in 14 the patient came to operation with a diagnosis of unclassified abdominal tumor. In 2 cases a diagnosis was based on a pathological report made subsequent to operation elsewhere.

The complaint of enlarging abdomen or the discovery of a mass by the patient was most common and occurred in 28 of the 42 cases. Abdominal pain or discomfort was noted in 20 cases, dyspepsia in 11, loss of weight, strength, and appetite in 11, constipation or diarrhea in 8, nausea and vomiting in 4, and swollen testis in 1 case. Examination disclosed a palpable mass in all but 1 case. In 7 cases the mass was on the right side and in 14 it was on the left. In 5 cases the entire abdomen seemed filled with the tumor and in 2 the mass was in the umbilical region. The upper part of the abdomen was involved by a mass in 1 case, and the lower part in 2 cases. There was little of diagnostic import in the laboratory data. Urological examination was made in 12 cases.

In 9 cases the mass was diagnosed as extrarenal. In 5 cases the diagnosis of renal tumor was made correctly and in 1 case the diagnosis of renal tumor was disproved at operation.

In all but 4 cases a transperitoneal approach was employed. In these 4 the usual incision in the loin for nephrectomy was used. Nephrectomy was performed six times. At operation the situation and attachments of these tumors were found to be as follows: in the right upper quadrant in 1 case, in the right side in 4 cases, in the right renal fossa in 7 cases, in the left upper quadrant in 1 case, in the left lower quadrant in 2 cases, in the left side in 5 cases, in the left renal fossa in 11 cases, in the entire abdomen in 5 cases, in the upper part of the abdomen in 1 case, in the lower part of the abdomen in 1, in the mesentery of the small or large bowel in 9 cases, in the pelvis in 3 cases, in the right kidney in 1 case and in the left kidney in 1 case. In 21 cases the tumor was thought to have been removed in its entirety and in 13 it was possible to remove a portion only. In 9 cases a small piece of tissue was taken for diagnosis.

The largest specimen removed was a fibromyxolipoma which weighed 47 pounds. In 35 cases the tumor was single and in 7 the tumors were multiple. The total number of tumors reported on was 61. Of these there were 21 lipomata, 6 fibrolipomata, 4 myxolipomata, 7 fibromyxolipomata, 1 myxoliposarcoma, 4 fibromyxoliposarcomata, 1 fibroliposarcoma, and 11 lipomata with sarcomatous change. Therefore 44 were apparently benign and 17 were definitely malignant. Infection or degenerative changes appeared in nine of the lipomata.

Of the 43 patients, 8 are living and well, the shortest 9 months and the longest 4 years since operation (average 2.3 years). Two other patients are living but have had a recurrence of symptoms 2 and 4 years after operation. Eight patients died in the hospital, 4 of bronchopneumonia, 2 of peritonitis, and 2 of shock and hemorrhage. Seventeen patients have died since operation, varying from 2 months to 4.5 years, and 7 could not be traced. Of 8 patients whose condition was malignant at the time of operation, 6 are known to be dead, 1 patient is living and well 5 months after operation, and 1 could not be traced. Twelve patients had recurrence. Six of these had manifested malignant change at the first operation and of these 5 are dead and 1 is living 10 months later. Six patients had recurrences there had been no evidence of malignant change at the first operation, and of these 5 are dead and 1 is living 3 years later. One of these patients was

operated on four times and one three times for recurrence.

In addition there were 14 cases in which intrarenal lipomata were found at postmortem examinations. These growths usually were small, cortical or subcapsular fatty nodules of no clinical significance.

Comparison of our data with those in the literature shows in general fairly close agreement. It will be noted that the condition is more common among women, that the diagnosis is seldom made before operation, that operative mortality is high (19 per cent in our series) and that recurrence is fairly common (14 per cent in our series of benign lipomata and a total of 28.5 per cent in cases showing malignant change at the time of the first operation).

The following report of a case is of interest because of the pararenal anatomical position of the growth and its probable intrarenal origin.

A woman, aged 36 years, came to The Mayo Clinic September 14, 1931, complaining of intermittent attacks of diarrhea, occasionally with generalized abdominal cramps, of 1 year's duration. The attacks occurred about once a month and lasted 1 or 2 days. Blood or mucus had not been noted in the stools. Her general health otherwise was good. The appendix and a cystic right ovary had been removed elsewhere, and splenectomy had been advised.

General examination was essentially negative, except for a tumor in the left upper quadrant of the abdomen. The mass, although not altogether typical of a spleen, still had more characteristics of an enlarged spleen than of a kidney or a retroperitoneal tumor. Urinalysis was negative. The concentration of haemoglobin was 78 per cent, erythrocytes numbered 4,510,000, and leucocytes 2,800 in each cubic millimeter of blood. The patient pretested intravenous pyelograms made elsewhere which apparently excluded the kidneys.

A diagnosis of tumor of the left side of the abdomen was made, with splenomegaly as the most probable pathological condition and retroperitoneal tumor as the second. September 23, 1931, the patient was operated on through a left rectus incision. A large retroperitoneal tumor was encountered. When the posterior sheath of the peritoneum was opened the tumor was brought into view. It was definitely encapsulated, about 75 or 80 centimeters in diameter, fairly movable, irregularly oval, and yellowish. The mass separated readily with minimal bleeding from adjacent structures except at its attachment in the lower pole of the left kidney. Here, because of its firm attachment to the kidney, it was deemed best to remove the tip of the lower pole of the kidney with the tumor. On palpation of the vessels in the pedicle of the kidney, it seemed as if the blood supply were greater than usual. The retroperitoneal space was then drained through a separate incision in the left loin. General abdominal exploration gave negative results. The patient had an uneventful convalescence and was dismissed from the clinic October 13, 1931, in good general condition.

The pathologist described the specimen as a pure retroperitoneal lipoma weighing 850 grams and measuring 15 by 5 by 22 centimeters, with a small portion of the kidney. Grossly the tumor was a smooth, soft, light yellow ovoid encapsulated body. Cut section revealed very little fibrous

tissue and no large blood vessels (Fig. 7). At its upper end it was attached to the tip of the lower pole of the kidney (Fig. 2). The renal capsule stripped freely except at this point of attachment. Several sections were cut from this site and stained with hematoxylin and eosin for microscopic study. Sections were also taken from other portions of the tumor. These showed that the tumor was composed mainly of adult adipose connective tissue (Fig. 3) with here and there small islands of cells having a stainable cytoplasm, small, densely stained nuclei, and a variable number of lipid droplets (Fig. 4). These cells conformed in morphology and staining reactions with embryonic types of fat cells. Connective tissue was scanty and when present was arranged around blood vessels. In the sections taken through the site of the attachment of kidney to tumor the areas suggesting embryonic fat cells were more numerous (Fig. 5) but the most striking feature was the presence of large blood vessel in the tumor adjacent to the parenchyma of the kidney (Fig. 6), strongly confirming the supposition that at least a goodly portion of the blood supply to the tumor came directly from the blood vessels of the renal cortex. The tumor was also in direct continuity with the cells of the renal cortex, the capsule at this point being absent and on the margin being reflected up over the tumor. These facts lead us to conclude that we were dealing with a true intrarenal lipoma. In spite of its gross anatomical paranrenal situation.

In the interest of accurate pathological classification we suggest that tumors of this type shall be subjected to careful histological study. It is possible that some of the cases in the literature reported as perirenal lipoma are actually as in this case intrarenal at least in origin. In this connection the observation of increased vascularity of the renal pedicle made at the time of operation is of particular interest.

THE ADMINISTRATION OF PROCTOCLYSTERS

GEORGE L. PERUSSE, JR., M.S. M.D. CHICAGO

REQUESTS have been made from time to time for information as to the best methods for the administration of proctoclysters. It would seem that of all hospital procedures designed to aid the patients in a time of acute need, this is the most slighted and neglected. John B. Murphy in his dissertation on peritonitis in 1908 describes a method of administering fluids per rectum which cannot be improved upon to this day. Some difference of opinion may be expressed on the duration of such administrations of fluids as well as in the choice of fluid used but the procedure is certainly excellent. We are all familiar with the sight which greets us on entering the room of the patient receiving proctoclysis. There is the vacuum flask perched on the uppermost rung of a stand with fluid running into the patient 40 to 60 drops a minute, without the slightest regard as to whether the patient is absorbing the fluid at the rate at which the drip is set. Soon we see that the patient has soiled his linen and is complaining of great distress. The nurse complains that nothing can be done with the patient. (A glance on the inside of the tube would probably show that the pressure was 15 to 25 inches of water pressure.) The attending surgeon then loses patience with the method and orders hypodermoclysis. Allow me to quote an excerpt from Murphy's original paper on the subject. "The fluid should be administered through a fountain syringe to which is attached a three-eighths inch rubber hose fitted with a hard rubber or glass vaginal douche tip with multiple openings. This tube should be flexed to almost right angles 3 inches from its tip. A straight tube must not be used as the tip produces pressure on the posterior wall of the rectum when the patient is in Fowler's position. The tube is inserted into the rectum to the flexion angle and secured in place by adhesive strips binding it to the side of the thigh so that it cannot come out. The rubber tubing is passed under the bedding to the head or foot of the bed, to which the fountain is attached. It should be suspended from 6 to 14 inches above the level of the buttocks and raised or lowered to just overbalance hydrostatically the intra-abdominal pressure, i.e. It must be just high enough to require 40 to 60 minutes for $1\frac{3}{4}$ pints to flow in, the usual quantity given every 2 hours. The flow must be controlled by gravity alone and

never by a forceps or constriction on the tube, so that when the patient endeavors to void flatus or strains, the fluid can rapidly flow back into the can, otherwise it will be discharged into the bed. It is this ease of flow to and from the bowel that insures against overdistention and expulsion onto the linen. The fountain had better be a glass or graded can so that the flow can be estimated. The temperature of the water in the fountain can be maintained at 100 degrees by incasement in hot water bags (or by partial immersion of an electric light globe). The fountain is refilled every 2 hours with $1\frac{3}{4}$ to 2 pints of solution. The tube should not be removed from the rectum for 2 or 3 days. When the nurse complains that the solution is not being retained, it is certain that it is not being properly given, even children retain proctoclysis surprisingly well.

McClanahan in his modification of Murphy's method, uses merely an irrigating can and a rectal tube with the end cut off. The can rests on a table beside the patient's bed which is on a level with the patient's rectum. Care is taken that the level of the fluid in the can is at no time more than 4 inches above the level of the rectum. The rectal tube extends from the can, under the bed clothes into the patient's rectum. It is not necessary to regulate the flow because a constant to and fro movement is maintained between the bowel and the can.

The great disadvantage to any arrangement such as Murphy and McClanahan describe is that the nurse is required to maintain the fluid level of the solution used, to obtain the best results. It cannot be too strongly stressed that herein lies the success or failure of proctoclysis in any given case.

Recently there has appeared on the market a cylinder can with a vacuum container and a visualizer tube on the outside, which enables one to see the level of the fluid within the reservoir. It is the writer's practice to suspend this device at such a height that the visible level of the fluid in the can is about 4 to 8 inches above the patient's rectum. The cylinder can is suspended from a stand which may be raised or lowered by means of a crank. Every half hour or so the can is raised to maintain the original pressure if the patient is absorbing the fluid readily.

The preliminary treatment to proctoclysis must always include a thorough emptying of the

bowel by means of an enema. This is done practically routinely in all the hospitals as a pre-operative measure.

The introduction of fluid within the bowel is accomplished by means of the largest size catheter possible to obtain which is pushed about 6 inches within the anal ring. The fluid of choice is a 1 per cent glucose solution which is very readily absorbed and non-irritant.

The maintenance of the temperature of the clyster solution is not of the greatest importance in this type of administration of fluids because the amount of fresh fluid introduced into the bowel at any one time is very small. Thus even at a rate of flow of 10 cubic centimeters per minute into an original volume in the bowel of 200 to 300 cubic centimeters the temperature change is small. However the solution must be at body temperature when first administered.

The clysis is run in 4 hour periods with a 2 hour rest period in between. At the end of the 2 hour rest period following two courses of clysis it is customary to give the patient a 1-3 enema for cleansing purposes. Thus accumulated fecal material and flatus which has not been expelled through the solution may be removed. Such administration of fluid may be carried on indefinitely without the slightest distress to patient.

We have observed from time to time that the fluid does not readily enter the rectum at the beginning of the procedure. The difficulty may be overcome by lowering and raising the reservoir 15 to 25 inches above the level of the rectum several times. The increased pressure causes the walls of the bowel to fall away from their close approximation. The can is then set at the level at which the fluid just begins to flow into the bowel (4 to 8 inches).

If it is necessary to make use of the type of vacuum bottle which employs a drip visualizer, the midpoint of the latter may be set at the required height above the rectum and the level observed when the tube is filled, may be maintained. If desired a very simple device may be employed which gives excellent results. A glass percolator may be used for the actual administration of the clyster and the vacuum bottle with the drip visualizer may be utilized to maintain the level in the former. The end of the tube from the visualizer is run under the surface of the fluid in the percolator so that warm solution is constantly coming in. The opening in the top of the percolator may be lightly wadded with cotton, and the level of the fluid is maintained at 4 to 8 inches above that of the rectum.

Fig. 1. The line 1 indicates the level at which fluid must be maintained in the reservoirs D or K, when either of these is used alone. This level is 4 to 8 inches above the patient's rectum. The line 2 indicates the level of the fluid in apparatus I when used in connection with D. C is the stand, L an air vent, F a screw clamp, G a drip visualizer, H cotton wadding, J tube to patient's rectum, K visualizer tube of K. The level in I is also 4 to 8 inches above the rectum.

The following rules governing the use of proctoclysters are suggested:

1. Be sure that the pressure employed is just sufficient to overcome the intra abdominal pressure (4 to 8 inches).
2. Be sure that the solution used is non-irritant and readily absorbed. (A 1 per cent glucose solution is excellent for the purpose.)
3. Be sure that the patient's bowel is cleansed at regular intervals.

THE CLINICAL AS DISTINGUISHED FROM THE LABORATORY EVALUA TION OF FACTORS INVOLVED IN HEALING OF INFECTED WOUNDS

IN his book, *Medical Education* Dr Abraham Flexner directs our attention to the fact that there is a science of medical practice no less important than the science of the laboratory. This comment appears to apply especially to the treatment of infected wounds. Lessons learned from practice have quite generally been set aside in such cases while technical laboratory methods difficult of clinical application have been brought to the bedside. A field in which this change has given many poor results is that of compound fractures. We are fully aware that reduction of the fracture accurate maintenance of length and position and immobilization are essential to good results. In all of the customary antiseptic methods, however plaster-of-paris casts are barred and splints are disturbed or removed in order that irrigations, fomentations, and such measures may be carried on.

In 1616 Cesare Magati of Scandia published his celebrated work *de Rara Medicatione* in advocacy of an infrequent dressing program for wounds. Magati lacked only the knowledge of infectious organisms and of the modern skeletal fixation devices and plaster of paris for the protection of the wound and the patient to lead him to the position that we are reaching only today.

Belloste, a French military surgeon adopted the teaching of Magati and gave him full credit (contrary to an Italian notion) for his contribution to surgical practice. John Hunter in speaking of compound fractures, said "a variety of inventions have been employed to prevent the motion" (of the fragments) "but the dressing of the wound every day counteracts the effect of every invention that has been thought of and it is perhaps impossible to dress the sore without motion."

Lister's application to surgery of the germ theory of Pasteur was first designed only to exclude infection from the wound. The original Listerian idea was soon changed to a plan of treatment calculated to combat the organisms in the wound. This altered antiseptic program, the many variations of which have had their origin usually in the laboratory has led us from one excess of antiseptic activity to another until it culminated finally in the Carrel Dakin method during the war and now in the "viable antiseptic" or maggot treatment. All of these antiseptic methods are open to the objections that they expose healing wounds to trauma and infection, that they disturb traction and immobilizing apparatus which are necessary for all inflamed and injured parts, and that they disregard all

fundamental rules of practice regarding drainage rest, and protection of the wound and the patient

During the past ten years a different "method of management" has come to be widely employed a method in which infrequent dressings have been systematically combined with adequate drainage with protection of the wound surface against re-infection injury by instruments drainage tubes or chemicals and with prolonged immobilization of inflamed or injured parts in plaster-of-paris casts

Statistics have now accumulated to show that by this mode of treatment in osteomyelitis, compound fractures and other infected wounds rapid and sound healing is obtained in a high percentage of cases. There is a great reduction in suffering for patients and substantial economies are effected in labor and hospital costs. Patients leave the hospital in a few days and dressings are done at intervals of weeks or even months instead of daily or oftener as heretofore

The operative and dressing technique are designed for adequate drainage and the protection of the wound surface by means of a non absorbent non irritating pack with the wound left wide open. No drainage tubes, stitches, or chemicals are employed in the wound, and no postoperative dressings are done for several weeks so that healing may be well established before the wound or the injured or inflamed parts are disturbed in any way

This, it will be seen is a clinical rather than a laboratory program. Tests of chemical agents counts of organisms and their reaction upon each other are disregarded. Inspection and explorations of the wound and the wound area are specifically precluded by the closed cast and entire reliance is placed upon the symptoms of pain swelling temperature

leucocytosis, and general appearance of the patient either for satisfaction as to patient's progress or for warnings of complications

Some laboratory studies already made suggest that alterations in virulence of the organisms after long intervals without change of dressings the presence of bacteriophage, or the purely physical effect of the petrolatum dressing medium may be of interest in connection with the healing of these wounds. From the purely clinical point of view, however it appears that the program of protecting the patient by minimal surgical procedures by guarding the wound surface against trauma chemical irritants and infection, and by immobilizing the nervous and vascular parts as well as the bones and joints in correct position for immediate as well as ultimate function may be the important factors that conduce to recovery. That is, the patient is placed in the best position and the injured and inflamed parts are surrounded by the most favorable conditions for the patient to set up and employ his own processes of repair. What happens in the wound and under the dressing therefore is of secondary importance to the patient though it may be of great academic and scientific interest to the laboratory technician and the surgeon. The principal forces of clinical scientific interest and of greatest importance to the patient are those operating within himself, and these probably supply all of the active healing agents and principles that appear in and about the wound

It is a maxim among clinicians that in diagnosis the laboratory and other instrumentalities do not establish but simply serve to confirm the clinical impressions. Perhaps we should reclaim this point of view for therapy, making sure that the laboratory point of view remains subservient and ancillary to the clinical. Such at least, appears to

be the lesson which we have learned in the treatment of infected wounds

H. WENNETT ORR.

PROGRESS AND PROSPECTS OF ROENTGENOLOGIC DIAGNOSIS IN RELATION TO SURGERY AND CLINICAL MEDICINE

LATE in 1895 came Roentgen's announcement of his discovery of roentgen rays, which brought to vision an aid scarcely second to that afforded by the microscope. Then began a stupendous advance in the diagnosis and treatment of disease of man.

At the outset, employment of the roentgen rays in medicine was a separate and special art. Roentgenological examination, with its savor of mechanics, was somewhat beneath the dignity of physicians of the old school and its early applications were relegated to lay tinkers with electricity or photography and to a few physicians who found pleasure in the study of electric and actinic phenomena. These men were the first roentgenologists. But soon every physician was imbued with the desire to make use of this diagnostic agent which, from all accounts, must be simple to use and probably capable of exhibiting the internal structures of the body as clearly as the furniture in a room can be seen through an open door. Thousands of physicians installed roentgenological equipment. Disillusionment followed speedily. Generating apparatus was capricious, and vacuum tubes were temperamental. To produce a roentgenogram a tediously long exposure was required. Roentgenograms were disappointing, scarcely more than the outline of the bones could be seen. Internal organs and soft tissues cast a confused aggregation of shadows which defied separate identification.

Apparently the game was not worth the candle, and most machines were consigned to

the attic. Thus, roentgenology was handed back to its pioneers, who continued faithfully to carry on. Today their names stand out vividly on the medical roster.

About 1910 the efforts of these pioneers began to yield conspicuous results. The medical world awoke to the realization that the roentgen rays were good for something more than to disclose the presence of fractures and foreign bodies. From that period on roentgenological diagnosis bounded forward. Now whatever the diagnostic problem may be, roentgenological examination is almost certain to be invoked for its forthright solution, for confirmation of the clinical opinion, or for the revelation or exclusion of hidden complications. Withal let it be noted well that with few exceptions the achievements and capabilities of roentgenology are due to the efforts of men who have applied themselves persistently and solely to this line of endeavor—roentgenologists.

In view of its progress in the past, there would seem to be little reason for concern as to the future prospects of roentgenology. Nevertheless, most of its practitioners, including those who are not apprehensive as to their personal welfare, regard the general outlook with anxiety for they are doubtful that the integrity and efficiency of roentgenology will be maintained. In too many instances the roentgenologist apparently is still regarded as a supertechnician rather than as a medical consultant. Too often his work, both technical and interpretive, is subjected to irksome supervision by his clinical and surgical associates. From every quarter he sees invasion of the roentgenological field threatening partition of its domain. Many surgeons, clinicians, and specialists prefer to employ roentgen rays directly or make their own interpretations, or entrust technicians with diagnostic responsibility even when competent roent-

genologists who could render better diagnostic service are at hand. As a further affront many young but thoroughly trained roentgenologists are driven by circumstances to accept full time employment at an extremely modest salary in certain open hospitals which appropriate all profits from the department although professional opinion now effectually bars similar employment of a surgeon, internist or otolaryngologist. Moreover by permitting any such practice in the roentgenological department, other specialists may be preparing a like future for themselves.

If it be granted that the foregoing conditions are widely prevalent, non-roentgenologists would perhaps offer the following pleas in justification. Roentgenology is not properly a specialty, for it covers virtually the entire field of medicine. To practice it efficiently the roentgenologist would need to be a universal specialist. Its foundations are not only too broad but also too shallow. Roentgenological data alone are not sufficient for diagnosis but must be construed in the light of the clinical facts. With his superior knowledge of these facts, the clinician has an advantage in interpretation. In essence roentgenological diagnosis is not analytic and rational but empiric and pictorial. Its fundamentals are simple, standardized, widely published and readily available to all. If equipped with a knowledge of them or with merely an atlas, the clinician should not require expert assistance in diagnosis. In short the roentgenologist is a superfluous intermediary, for no one can gainsay the right of any physician to use roentgen rays, and he should learn to employ them just as he has learned to use other means to aid his vision.

To all such claims the roentgenologist would oppose an emphatic dissent and might argue as follows. Roentgenology represents a logical division of labor in the evolution and higher

organization of medical science and art. It has the same tripartite foundation that underlies all medicine and all specialties in medicine, namely, anatomy, physiology, and pathology. A thorough understanding of these basic sciences is related to roentgenological phenomena is indispensable. Its efficient practice necessitates instruction and experience at least equivalent to those required for the practice of any other specialty. It is not true that clinical data enter primarily and inevitably into roentgenological interpretation, nor is it true that advance acquaintance with the clinical facts in a given case will assist the roentgenologist in the discovery or exclusion of disease. On the contrary, his prime task is a study of anatomy, physiology, and gross pathology as depleted by shadows and shadow-defects regardless of symptoms and physical signs. His study is not merely pictorial and comparative but highly analytic, and roentgenological advancement has been achieved almost exclusively by this method. Through repeated humiliations he has learned that foreknowledge of clinical facts will bias his judgment and lead him too often into error. In this factor he sees an insuperable obstacle to reliable roentgenological diagnosis by the clinician, and he holds it accountable for a large proportion of current mistakes. He freely admits that clinical facts are often necessary for differential diagnosis but in such instances he is confident that the best results will follow a review of their respective data by the roentgenologist and clinician in personal conference. For these reasons the roentgenologist feels strongly that to distribute his province among other specialties would be atavistic, degenerative, and a futile repetition of history.

Thus the issue is joined, an issue without rancor or bitterness but none the less an issue. It must be and will be settled without regard for the dignity, fame, or emolument of any

person group or guild for the spirit of trade-unionism has no place in it. It would doubtless determine itself in the natural evolution of medicine. If roentgenologists have been remiss in acquiring and maintaining the proficiency rightfully expected of them, if realities are lagging too far behind ideals, or if competent roentgenological diagnosticians are still too few the condition should be corrected. But whether a proper settlement shall be for-

warded or retarded depends not only on the roentgenologists but also on the attitude of the profession of which they are a part. The fact that an issue exists at all is conclusive proof that neither group fully understands the other and a program of mutual enlightenment should be inaugurated. This done, holding fast to the high purpose of all medical endeavor a fair and final solution will be well on its way.

B. R. KIRKLEY

DANIEL BRAINARD
1812-1866

MASTER SURGEONS OF AMERICA

DANIEL BRAINARD

THE first great surgeon of Chicago and the northwest was Daniel Brainard. Brainard was born in 1810 to the state of New York where he received his early education. He graduated at Jefferson Medical College in 1834. He settled in Chicago in 1836 when it was a town of about 5,000 people. He had great confidence in the future of Chicago and the west and believed that they would become great and prosperous communities. He believed that such a future demanded the development of schools and colleges and professional schools and as early as 1837 he secured a charter for a medical school which he named after Benjamin Rush, a signer of the Declaration of Independence and the father of American medicine. He went to Paris, which was then the center of medical education, in 1839 and remained until 1841 doing post graduate work. He then returned to Chicago and organized Rush College which began to give medical courses in 1843.

Daniel Brainard began his medical career just before or at the very beginning of the period which is usually recognized as the period of modern medicine, the date of which is approximately 1850. In order to visualize this period let us recall the prominent medical figures of that time. Paris was generally regarded as the center of medical education. Here Claude Bernard (1813-1878) was teaching physiology and medicine. Cruveillier was teaching pathology and creating his great atlases of pathology. Armand Trousseau, one of the greatest clinical teachers, was giving his wonderful clinics in medicine. Larrey, Napoleon's great military surgeon, was still living. Brainard's teachers of surgery were the great French surgeons Velpeau 1795-1867, Malgaigne 1806-1865, Nélaton 1807-1873. In England the great clinicians in medicine, Graves 1796-1853, Stokes 1804-1878, Bright 1789-1854, Addison 1793-1860, and Hodgkin were at work advancing medical knowledge and making medical history. In surgery, James Syme 1799-1870, William Ferguson 1808-1877, Sir Benjamin Brodie 1783-1862, Sir James Paget 1814-1899, were the leaders of British surgery of Brainard's time. In Germany Bernhard Von Langenbeck 1810-1887 and Gustav Semmow were the great teachers of surgery, and in Russia Pirogoff, the great military surgeon was the recognized leading surgical teacher and one of the most prominent figures in Russian medical history.

Charles T. Parkes, Nicholas Senn, John B. Murphy, and others—and Brainard's old clinic has continued to grow stronger and stronger with the passing years and with the great development that has taken place in anatomy, physiology, and pathology, which still continue to form the foundation on which the clinic is built.

Daniel Brainard founded a surgical clinic that has become an important factor in American surgery. One of its functions which has become a tradition in the clinic is the training of younger men to become teachers of surgery. In this it has been successful as shown by the fact that a number of the most important surgical chairs in this country are now filled with men trained in the clinic which Brainard founded.

We can obtain a good idea of the estimate of Brainard's work by the men who shortly succeeded him from an address delivered by Nicholas Senn when he assumed the professorship of surgery founded by Brainard. He said: Brainard, the founder of this institution and the first occupant of the chair of surgery, was a great surgeon, a gifted teacher and an original investigator. His giant intellect was not content in acquiring, practising, and teaching what was known at his time, but sought new fields for exploration, and the knowledge thus gained was freely infused into his students. Brainard's work in the field of experimental surgery brought him an international fame. His work left numerous permanent impressions on surgical literature; it created a stimulus which took possession of students and progressive surgeons throughout the world, leading them into new and unexplored territories.

ARTHUR DEAR BETTS

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE book on *Orthopaedic Surgery*¹ by Walter Mercer is an elaboration of lectures and clinics on orthopaedic subjects conducted by the author at the University of Edinburgh the Edinburgh Royal Infirmary and other hospitals. The writer is associated with Prof. or John Fraser who has written the foreword. There are eighteen well arranged chapters covering about seven hundred pages.

The introductory chapter covers the history, definition and scope of orthopaedic surgery and briefly discusses the routine examination in an orthopaedic case and the technique of plaster-of-paris work. A concise chapter on congenital deformities follows. The next chapter on general affections of the skeleton includes nutritional and glandular disturbances. Referring to generalized osteitis fibrosa cystica the author discusses briefly the recent work on associated lesions of the parathyroid glands. Quoting Turnbull he states that the nature of the parathyroid enlargement is never neoplastic but that histologically the gland presents the picture of functional overactivity. The author describes Fraser's classification of primary bone tumors dividing them into simple border line malignant and tumors of unknown origin. Metastatic tumors and inflammatory conditions are omitted.

A chapter is devoted to tuberculosis of bones another to tuberculosis of joints and another to non-tuberculous infections of joints due to specific infections such as pyogenic pneumococcal and gonococcal arthritis and Charcot's disease.

Chronic arthritis is described under two main types without adding further confusion to the numerous and frequently confusing classifications presented in recent literature.

Chapters on epiphyseal affections of the spine shoulder knee and foot contain comprehensive descriptions. The chapters on complications of trauma and affections of soft tissues emphasize the advantage of the general surgical training of the author.

The bibliography is copious and explicit being arranged according to chapters and affections described.

The book is concisely and systematically written and generally well illustrated although some of the roentgenograms could have been better chosen. The line drawings (done by the author's wife) accomplish the purpose for which they are intended although

done by one who evidently does this work as an avocation. Future editions may refer to Morrison's bipp treatment of osteomyelitis the work of Crowe Hadjapoulos Burbank and others in the vaccine treatment of arthritis and Galeazzi in the treatment of scoliosis. In discussing recurrent dislocation of the shoulder Nicola's operation should be included. However one cannot expect everything to be included in such a concise volume. The merits of this book warrant its addition to the libraries of students practitioners and orthopaedic surgeons.

DANIEL H. LEVINTHAL

IN this interesting volume on surgery of the stomach and duodenum² Rhaume endeavors to present the operative procedures as practiced in North America in connection with the diseases of these organs. The first four chapters are devoted to the evolution of gastric surgery anesthesia topographic anatomy and the pre-operative treatment. The remaining twelve chapters describe in detail typical procedures upon the stomach and duodenum.

The contributions of the American surgeons are given a prominent place. The operative procedures are illustrated with drawings frequently borrowed from well known sources such as the Mayos, Balfour Coffey and others. Each chapter is supplemented with a small but well chosen bibliographic index in which the names of American surgeons predominate. The entire subject matter is admirably presented and will no doubt stimulate much interest among the continental French surgeons.

GEORGE HALPERIN

THE first edition of this work³ (1911) by the present professor of anatomy at McGill University was prepared from lectures given to candidates for the Oxford diploma of ophthalmology. The lectures were illustrated with dissections and numerous photographs of these add greatly to the value of the book, which is the only extensive treatment of the subject in English. The 1932 edition contains 19 additional illustrations, chiefly of dissections and 39 pages of additional text. No chapters have been added the additions being made necessary by 190 contributions to the literature during the past 20 years which required consideration in the book.

¹TECHNIQUE ORTHOPÉDIQUE ESTOMAC ET DUODÉNUM. By Pierre Rhaume. Paris, Masson et Co 1931.

²THE ANATOMY OF THE HUMAN ORBIT AND ACCESSORY ORGANS OF VISION. By S. Ernest Whitnall, M.A., M.D., F.R.C.S. (Oxon.) M.R.C.S. (L.R.C.P. (Lond.)) 2d ed. New York and London: Oxford University Press, 1931.

³ORTHOPAEDIC SURGERY. By Walter Mercer M.B., Ch.B. F.R.C.S. (Edn.) F.R.C. (Edn.). With a foreword by John Fraser M.C., M.D., Ch.M., F.R.C.S. (Lond.) London: Edward Arnold & Co., 1933

About one-fourth of the book is devoted to the bony orbit and its relation to the accessory sinuses, a third to the eyebrows, lids, conjunctiva and lacrymal apparatus and the remainder to the globe extra-ocular muscles, nerves and cerebral pathways. Not only is the normal anatomy of the parts considered, but their development, common anomalies, and the normal changes which occur during life. We are reminded, for instance, that the roof of the orbit varies from 1 to 4 millimeters in thickness, and that it is often of such paper like delicacy that a tap with the finger nail will break through it and dehiscences due to a trophy of the bone in old age may be present, the peri-orbita then lying in contact with the dura. Similar dehiscences may occur in the floor of the orbit whereby the contents are only separated from the lining of the maxillary sinus by the peri-orbita. The variations in the sinuses, which are of especial importance in the relations of the lacrymal sac, are well discussed.

The question of the involuntary orbital muscles of the orbit and their possible importance in the mechanism of exophthalmos is fully treated. This point, surprisingly enough, has never been settled for ophthalmologists. In the region of the inferior orbital fissure is a mass of smooth muscle fibers fused with the peri-orbita. This is the "orbital muscle of Mueller" innervated by the sympathetic, which has been thought to protrude the eye by becoming thicker during contraction. The author points out that while in animals it may be of importance, in man it is purely vestigial and excitation of its sympathetic innervation does not cause protrusion of the globe. It is too small, he concludes, to cause pro-

trusion of the globe by pressure on the orbital contents and the veins which pass through it are too small to produce the same effect by their occlusion. The other muscle which has been considered of importance in exophthalmos and which is often referred to as the protrusor bulbi, is the peri-bulbar muscle or *musculus capsulo-palpebralis* of Landström. Landström's muscle, it may be noted, is erroneously figured in Bing's *Gehirn und Auge* as being at the apex of the orbit, evidently by confusion with the orbital muscle previously described. (Reviewer's note) Landström's muscle itself extends as a membrane around the anterior half of the globe, being continuous anteriorly with the involuntary muscles of the lid. Since it lies mainly in front of the globe the author evidently does not believe that its contraction could cause exophthalmos, although it could, as Adler apparently proved, raise the intra-ocular tension by compressing the globe. He believes the most probable cause of the exophthalmos in Graves' disease is dilatation of the orbital blood vessels by excitation of the sympathetic nervous system. He has dissected two orbits of patients dying of Graves' disease without finding anything abnormal.

In the section on the cerebral pathways, modern work, especially that of Brommer on the visual pathway and the retinal representation in the occipital cortex, receives careful discussion.

The format of the book and its illustrations are up to the best standards and the work forms a fitting companion to J. Parsons Schaeffer's work on the nose and paranasal sinuses in the library of anyone practicing surgery of the head as well as of the ophthalmologist. SAMUEL R. GITTON.

POSTOPERATIVE PULMONARY SUBVENTILATION¹

MI PRINZMETAL, M A S BRILL, M D² AND C D LEAKE, PH D SAN FRANCISCO, CALIFORNIA

Abdominal section is a bit below the belt and the patient is always winded by it —W Pasteur 1910

THE significance of atelectasis as an important postoperative complication is now well recognized. The numerous factors which play a part in the production of atelectasis have been discussed previously (4). It is our purpose here to indicate some of the causes of pulmonary subventilation and to point out the relationship between this condition and postoperative atelectasis.

The etiology of atelectasis has attracted the attention of many workers. It is now fairly well accepted that atelectasis results from bronchial obstruction as shown by the work of Coryllos and Birnbaum, Brunn and Brill and others.

It is generally recognized that it is an upper abdominal operation that predisposes to atelectasis. Sise (21) for example found that postoperative lung complications occurred after 0.5 per cent of operations on the extremities, 1 per cent after operations on the lower abdomen and 10 per cent after operations on the upper abdomen. A L Brown (3) and others have found a similar distribution. Studies on the vital capacity have given parallel findings (8). Head for example found an average reduction in vital capacity of 8 per cent after hemorrhoidectomy while it was reduced from 78 to 88 per cent after

operations on the stomach. It was first thought that such a fall in vital capacity after abdominal operation was due in part to the pain of vigorous respiration following surgery. But Sise (22) has pointed out that the deep respiration induced by carbon dioxide inhalation does not cause excessive pain in the postoperative patient.

William Pasteur (16) in 1908 showed that there was a limitation of motion of the diaphragm after upper abdominal operations. Recently Muller Overholt and Pendergrass (14) studied this question more thoroughly in 25 selected cases of upper abdominal operations on the stomach and gall bladder. They found diminished expansion at the bases of the lungs in all cases; in 80 per cent there were suppressed breath sounds; in 20 per cent bronchial breathing; and in 56 per cent rales. Yet only three of their patients had cough and dyspnea. They concluded that these changes can be considered as a normal accompaniment of every upper abdominal operation and named the syndrome pulmonary hypoventilation³.

We have been interested in the relationship between upper abdominal operations and these described changes in pulmonary physiology. Our method was to study in the same animal the effect on pulmonary compression of various surgical procedures such as anasthesia, abdominal incision, traction on ab-

¹Read before the sixteenth annual Clinical Congress of the American College of Physicians, April 7, 1932, San Francisco. From the Department of Surgery, Division of Thoracic Surgery and the Pharmacological Laboratory, University of California Medical School, and supported in part by the J. J. and Nettie Mack Foundation.

²A more consistent term would be pulmonary subventilation, and since the latter would also avoid the possibility of confusing "hypo" with "hyper" it was decided to employ it in this paper.

December 27, 1900—January 23, 1910. This paper is respectfully dedicated to the memory of Dr. Brill by his collaborators.

Fig. 1. Kymographic tracing of intrapleural pressure and respiratory movement in a normal unanesthetized dog. The downstroke in both tracings is made on inspiration and the upstroke on expiration. I.P.P. indicates intrapleural pressure. Figures are in centimeters of water.

dominal viscera, and pressure on the abdomen. The state of pulmonary compression or distention was determined by means of intrapleural pressure. Trochars were placed in the intrapleural cavities of the dogs, and by means of branched tubing both manometric and kymographic records were obtained. We also made blood pressure observations.

Figure 1 shows what may be considered a normal curve. As is well known intrapleural pressure is normally subatmospheric due to the stretch of the elastic lung tissue. During

inspiration as the thorax is enlarged, there is greater stretch and the pressure becomes more subatmospheric. During expiration it becomes more positive since the stretch is reduced but normally it is still subatmospheric. Thus, the greater the lung is compressed the more positive does the intrapleural pressure become. The more the lung is distended by a deep inspiration, the more subatmospheric or negative does it become. A pneumograph was placed on the dog's chest in order to determine the relative expiratory or inspiratory position of the thorax.

The first surgical procedure we studied was ether anesthesia (1). The effect is quite complicated (Fig. 2). At first there is violent respiratory movement which corresponds to the second stage of anesthesia. As the animal goes into the third stage of anesthesia, one notes a gradual and very definite rise in intrapleural pressure accompanied by a gradually decreasing thoracic girth. A rise in intrapleural pressure means less lung distention or relative lung compression. This may be due to paralysis of the intercostal muscles in the face of a constant lung elasticity for in deep third stage anesthesia the intercostal muscles can be seen to be sucked in during inspiration.

Abdominal incision further increases intrapleural pressure (Fig. 3). This might be explained by Overholt's theory that pulmonary subventilation is due to pneumoperitoneum which he thinks occurs after abdominal incision (15). The intraperitoneal pressure is normally subatmospheric and he has found it increases somewhat after abdominal incisions. Pneumoperitoneum occurs after many surgical procedures as can be seen in Figure 4.

Assistants often get tired during a surgical operation and may rest on the abdomen. This further increases intrapleural pressure or causes further lung compression as may be illustrated by reference to Figure 5. Clear evidence is here afforded of the possibly harmful effects of thoughtless leaning on a patient's abdomen during an operation.

Traction on any abdominal viscus like the stomach or mesentery further increases the pressure and causes more pulmonary compression (Fig. 6). It is suggested that

Fig. 2. Kymographic record of intrapleural pressure and thoracic girth in a dog showing effects of ether. The intrapleural pressure is increased and the thoracic girth decreased in deep anaesthesia.

during operations in which an organ is put on a continuous stretch there must be a marked effect on respiration.

To the question are these changes purely reflex and do they disappear after the abdomen is closed and anaesthesia stopped the answer is apparently no as may be deduced from data offered in Table I. Before surgery the intrapleural pressure was -3 centimeters water to -8 centimeters water. After the anaesthesia was stopped and the abdomen closed the pressure was $+3$ to -6 . The total increase in intrapleural pressure at the end of expiration in this case was 6 centimeters of water. The cause of the increased intrapleural pressure is probably the rise in the diaphragm which Pasteur (16) first described in 1908. A roentgenogram of a normal pre-operative chest is shown in Figure 7. After surgery it can be seen that the diaphragm has risen somewhat causing the heart to assume a more horizontal position but the mediastinum has not shifted (Fig. 8). It is the base of the lung that suffers most, and as a result bronchial breathing and râles might be heard in a case like

this. It should be emphasized that bronchial breathing diminished expansion and râles heard at the bases of the lung following abdominal surgery do not necessarily mean pneumonia.

Pulmonary subventilation also occurs in other conditions. Pasteur (17) in 1890 studied

TABLE I.—INTRAPLEURAL PRESSURE CHANGES IN DOG DURING GASTRO-ENTEROSTOMY

Time		Intrapleural pressure expiration cm. H ₂ O	Intrapleural pressure inspiration cm. H ₂ O
1:59	Before ether	-3	-8
2:00	Anaesthesia started dog struggling	$+3$	-20
2:05	Deep anaesthesia	$+2$	-7
2:20	Peritoneum opened	$+2.5$	-7
2:30	Gastro-enterostomy	$+3$	-6
2:40	Gastro-enterostomy	$+3$	-6
3:00	Peritoneum closed	$+3$	-6

Fig. 3. Kymographic record of intrapleural pressure and thoracic girth in a dog under ether anesthesia showing effect of opening the abdomen.

15 cases of diphtheritic paralysis of the diaphragm. He found percussion dullness and bronchial breathing in many of the cases but at autopsy he found atelectasis. Elderly patients who have been bedridden for some time due to such conditions as typhoid fever or fractured neck of the femur suffer from pulmonary subventilation. It also occurs in tympanites as is seen in this case (Fig 9). After the tympanites has been removed by suitable treatment the diaphragm again assumes its normal level (Fig 10).

The increased intrapleural pressure induced by surgery might be expected to have a profound effect on circulation. Physiologists have long recognized the importance of the negative pressure in the thorax in aiding venous return. An increased intrapleural pres-

Fig. 4. Pulmonary subventilation produced by a pneumoperitoneum after abdominal operation.

sure would therefore impair venous return. Lister has suggested that venous stasis is an important factor in the formation of post operative emboli. Kountz, Alexander and Dowell (10) found that the increase in intrapleural pressure in emphysema causes an increased venous pressure. The increase in intrapleural pressure causes a lowering of arterial blood pressure (Fig 11). Pulmonary subventilation might therefore be a factor in the lowering of arterial blood pressure found after surgery.

The pulmonary compression induced by surgery helps explain the decrease in vital capacity found after abdominal operations. Pulmonary compression is also an adequate explanation for diminished expansion, rales, and bronchial breathing or diminished breath sounds heard at the base of the lungs which Muller Overholt, and Pendergrass found after an upper abdominal surgery (14).

Carbon dioxide inhalations have been found to be a great aid in both the prevention and treatment of postoperative complications (4). Carbon dioxide causes a decrease in intrapleural pressure (20) to its normal subatmospheric level thus counteracting the effects of surgical procedures (Fig 12). If atelectasis

Fig. 5. Kymographic record of intrapleural pressure and thoracic girth in a dog under ether anesthesia showing effects of pressure on the abdomen. I.P.P. figures indicate intrapleural pressure in centimeters of water

has already occurred the decreased intrapleural pressure induced by carbon dioxide might be expected to help distend the collapsed lung. Of course there are other reasons why carbon dioxide is an efficacious treatment. It dilates the bronchi (2) raises blood pressure (11), and increases ventilation. The effect on intrapleural pressure seems almost specific in counteracting the harmful effects of surgery on pulmonary physiology.

What is the relationship between the conditions of pulmonary subventilation and obstructive atelectasis? It is suggested that pul-

Fig. 6. Kymographic record of intrapleural pressure in both chests and blood pressure showing effects of traction on the stomach

monary subventilation is an etiological factor in the production of real atelectasis. Lung compression and decreased ventilation will favor the accumulation of secretion and thus prevent proper lung drainage, thereby leading to the production of mucous plugs. The importance of diagnosing this condition and of administering the proper treatment is therefore evident.

The distinction between pulmonary subventilation and postoperative atelectasis is demonstrated in Table II.

Fig. 7. Roentgenogram demonstrating the normal chest of a patient before operation.

Fig. 8. Same patient as in Figure 7 after abdominal operation. Note increase in the height of the diaphragm and increased thoracic girth.

Fig. 9. Tympanites present after operation and producing pulmonary subventilation. Note the position of the diaphragm.

Fig. 10. Same patient as in Figure 9 showing return of diaphragm to a more normal position after the tympanites were relieved by enemas.

The increased intrapleural pressure offers an explanation for the decrease in vital capacity and the signs at the bases of the lung found after surgery. Carbon dioxide has been shown to lower intrapleural pressure and therefore to counteract the harmful effects of surgery on respiratory physiology. The relationship between pulmonary subventilation and obstructive atelectasis is pointed out.

We desire to thank Dr Harold Bruus for aid and advice.

THE RÔLE OF THE PLACENTA IN THE MAINTENANCE OF HYPOPHYSEAL ACTIVITY DURING PREGNANCY¹

HAROLD KLINCLER M.D. J. C. BURCH M.D. F.A.C.S., AND R. S. CUNNINGHAM M.D. NASHVILLE
From the Department of Gynecology and Anatomy Vanderbilt University School of Medicine

IT HAS been known for many years that the corpus luteum is an important physiological link in the mechanism of pregnancy. This fundamental fact in the physiology of the female reproductive mechanism has been established by a series of beautiful studies which were inaugurated by the epoch-making discovery of Fraenkel who at the suggestion of Professor Born investigated the effect of removing the corpus luteum on the maintenance of pregnancy. Fraenkel found that when the corpus luteum was removed from pregnant animals abortion took place. He concluded that this structure produced a secretion or hormone which acted directly upon the uterus to maintain the viable connection between the placenta and the maternal tissues. It is needless to review in detail the important contributions of Loeb (22-23), Bown and Ancel, Dubreuil and Regaud and others. All of these investigators have advanced additional evidence which has confirmed the essential fact that the secretion of the corpus luteum is of fundamental importance in the maintenance of pregnancy. The recent investigations of Corner and Allen (1-8) have added the final proof to this conception of the function of the corpus luteum. These investigators prepared an extract from corpora lutea which when injected into rabbits spayed shortly after mating allowed pregnancy to continue throughout its normal period. Furthermore with these extracts they produced typical progestational changes in animals previously sensitized by the injection of estrin. It seems fundamentally sound therefore, to accept as sufficiently demonstrated that the primary function of the corpus luteum is the production of a secretion which is essential in the establishment and maintenance of early pregnancy.

It has been found by repeated experiments both artificial and performed by nature that if nidation fails to occur the corpus luteum degenerates and disappears. Whereas if nida-

tion does occur, the corpus luteum is stimulated and continues to function. The mechanism of this activation of the corpus luteum has eluded final demonstration until recent years. It has been through a series of studies which have been developed largely from an entirely adventitious viewpoint i.e. the study of the anterior lobe of the hypophysis that definite progress has been made.

It seems logical to reason that the factor which is known to be most potent in its action on the ovary might be expected to be the link concerned with the activation of the corpus luteum. In the inception of the work which we wish to present in this communication, this process of reasoning lead us to consider that such a mechanism would in all probability be found to operate through the anterior lobe of the pituitary body since numerous brilliant investigations had demonstrated the profound and fundamental nature of the control exercised by this structure upon the female reproductive organs.

The capacity of the anterior lobe of the hypophysis to produce an effect upon the ovary was demonstrated independently in 1927 by Smith and Engle and by Zondek and Aschheim. These observers found that subcutaneous implantation of anterior lobe tissue into infantile mice brought about a rapid development of the genital tract, with the premature appearance of estrus, enlargement of the ovaries and specific changes in the uterine epithelium. The ovaries were most remarkable the follicles had undergone rapid development ovulation had taken place in many cases and corpora lutea had been formed. In addition, there were numerous blood filled follicles and, in some instances, luteinization had occurred in unruptured and even in immature follicles. In addition to being of fundamental physiological importance this reaction has been utilized as a practical basis for much of the subsequent work on the anterior lobe of the hypophysis and has con-

stituted an exceedingly delicate biological test for the presence of the hormone or hormones of this gland. It is not within the province of this paper to discuss the so called duality of the anterior lobe secretion or the possibility as suggested by Philipp and others that the hormone present in the urine of pregnant women is in reality a placental hormone. Studies have been carried out by Friedman Wolfe and others on the relationship between the hypophysis and ovulation. In all these investigations it has been repeatedly demonstrated that the anterior lobe possesses a very powerful capacity to stimulate the production of lutein tissue in the ovary under a variety of conditions. All of the studies which have been directed toward the solution of this particular problem have strongly supported the concept of a relationship existing between the anterior lobe and the corpus luteum.

The considerations just outlined lead to the assumption that there is probably some peculiarity in the state of pregnancy which increases the capacity of the anterior lobe of the hypophysis to stimulate the ovary and more especially the corpus luteum. It was on

this assumption that the experiments reported here were inaugurated and since it is obvious that the placenta is the most characteristic and pertinent structure developed during pregnancy it seemed probable that it would have some specific action on the anterior lobe. The same line of reasoning included the possibility of the controlling factor being decidual tissue or the fetus itself. The former was thought to be unimportant since the experiments of Loeb had demonstrated that the presence of experimentally produced placentaloma was insufficient to maintain the corpus luteum in a state comparable to the corpus luteum of pregnancy. The rôle of the fetus is easily excluded as a source of the unknown secretion by the consideration of hydatidiform mole and chorio-epithelioma. In these interesting conditions the endocrine activities of pregnancy are maintained after the fetus has been expelled from the body.

The capability of the placenta to produce a hormone was first suggested by Halban who from clinical observations, reasoned that the placenta was a gland of internal secretion. In the following year Lane-Clayton and Starling made a weak aqueous extract from placenta and fetus and found that this extract had a definite effect on the mammary gland. Later extracts potent in the estrus producing hormone were made by Hermann Jacovisco, Frank Allen and Doisy and many others.

The estrus producing substance furnished by the placenta has been studied extensively and it has been shown that this substance is similar to the hormone of the ovarian follicle in the biological reactions which it produces. In 1920 Hirose demonstrated that the intra-pentoneal injections of placenta produced marked changes in the ovaries of rabbits. The increase in number and size of the corpora lutea was especially noteworthy. These changes were obtained with fresh placenta, but were not obtained with the ether or acetone extracts. He also found that this effect was obtained only from placenta of the first half of pregnancy. Hirose's paper has not been available to us in the original; the information here given was obtained from the paper by Murata and Adachi who have confirmed and extended Hirose's experiments.

They found that if the animals had been previously spayed they could not produce an enlargement of the uterus by placental extracts, and concluded that the estrin content of placental material was not responsible for the change but rather that the placental material had in some way influenced the ovary to increase its own production of estrin. Zondek and Aschheim in addition to their discovery of the ovary stimulating hormone in the blood and urine of pregnant women found that implants of small amounts of placental tissue produced a somewhat similar action. Wiesner prepared an extract from human placenta by extracting it with sulphosalicylic acid which contained a considerable amount of the ovary stimulating hormone and also some growth hormone.

In considering the evidence presented it was felt that the mechanism for the maintenance of hypophyseal activity must reside in the placenta, the secretion of the placenta stimulating the hypophysis and that of the hypophysis in turn stimulating the ovary. With this thought in mind Burch and Cunningham carried out a series of experiments which were reported in a previous paper in 1930. These experiments were conducted as follows: A commercial alcoholic extract of placenta was obtained and this material was injected into a series of spayed rats. These rats were later killed and the hypophyses removed and transplanted into the subcutaneous tissues of infantile mice. The mice were given two transplants, each consisting of the entire anterior lobe from a rat which had been treated as already outlined. These mice were sacrificed on the fourth day and the genital tracts studied. A series of control experiments were also carried out. These consisted of mice into which hypophyses of spayed rats which had not been injected with the extract were transplanted. In these experiments it was found that the size of the ovaries in the animals of the experimental group were approximately three times larger than those of the control animals. These experiments are being reported in detail in this paper (see Tables I, II and III). The extract which was used was obtained in several shipments. The estrin content was carefully

Fig. 2. Drawing of ovaries, uterus and tubes of control mouse No. 41 702 after fixation in Bouin. This animal had an index of 2.6 which is approximately the average of this group. $\times 27$.

standardized as at that time estrin was considered to be the most important of the various substances known to be present in the placenta. This extract was prepared by alcoholic extraction of fresh human placenta and as it was in the experimental stage there was some variation in the method of preparation which however did not differ in the fundamental use of alcohol as a preliminary solvent. The variation in the method used in preparing the extracts may account for the marked variation which we obtained in the individual animals in this series of experiments. Kraus has approached the problem from much the same viewpoint as our own. He employed the histology of the ovary as a measure of the activity of the anterior lobe. He concludes that the follicular growth of animals receiving hypophyses from donor animals previously treated with folliculin or placenta extract is variable but sometimes increased.

Following our report, it was shown by Leonard, Meyer, and Hisaw that the ovary stimulating capacity of the anterior hypophysis was diminished by repeated injections of estrin over a long period of time. Kunde, d'Amour, Gustavsoo, and Carlson obtained

Fig. 3. Drawing of ovaries, uterus, and tubes of a perinatal mouse No. 46-835. This animal had an index of 6.7 and was one of the three largest of this group. Note the large horns on each ovary. $\times 6$

the estrin hormone from the urine of pregnant women and injected this daily into immature dogs over a period of 6 to 17 weeks. They found that the anterior lobes of these dogs were much smaller than those of normal dogs and that the ovaries were also smaller than normal. These experiments indicate very clearly that estrin could not have been the material that produced the changes which we observed in our previous experiments. It is to be noted here that we could not determine the nature of the mechanism involved and as stated in our paper "the stimulating effect produced on the anterior lobe was increased by an extract of placenta which contained a high concentration of estrin. The experiments referred to have clearly demonstrated that estrin could not have been the responsible agent in our previous extracts."

In 1930 there appeared a series of studies by Collip (5, 6, 7) on the placenta, which offered a wholly new line of approach and interpretation for the work which we have referred to. Collip has extended the studies of Wiesner and has, by means of alcohol, acetone and ether extractions, obtained three

Fig. 4. Photograph of normal animal No. 5-840 and experimental animal No. 46-835, after fixation in Bouin's.

fractions which are relatively specific in character. The original extraction was made with acetone. After concentration and removal of the acetone *in vacuo* he subdivided his fractions according to their solubilities in alcohol, ether and water. One fraction which he obtained contained estrin. The second he has called the anterior pituitary-like substance and has found that its action is biologically similar to the ovary stimulating hormone which is found in the urine of the pregnant and in the substance of the anterior lobe of the hypophysis. His third fraction he has called "emmenin." This substance has an estrogenic action which is not interfered with by the removal of the hypophysis. Evans, Meyer and Simpson have shown that the urine of pregnant women contains a substance which activates the hypophysis in regard to its ovary stimulating capacity. This substance they have designated as "prolan," after Zondek and Aschheim. It is possible that this is the substance which was the active principle in our original extracts. It seems from the experiments which we are reporting in the second part of this paper that our original hypothesis of placental stimulation of the hypophysis is correct and that the active agent is either emmenin or the substance resembling that from the anterior pituitary gland or a combination of one or both of these with estrin.

FIRST SERIES OF EXPERIMENTS

All of the tables are arranged in the same fashion and therefore a general statement

regarding the data included in them seems advisable. The ovaries were fixed in a uniform manner dehydrated and embedded as carefully as possible and serially sectioned at seven microns. The largest section was measured by a micrometer eyepiece which had been standardized against a micrometer slide and the number of sections obtained from each ovary counted and multiplied by seven in this manner three dimensions of the ovary were obtained which when multiplied together, gave the index. This index is not an accurate measure of size but we feel that it is more accurate for purposes of comparison than any other method which we have tried. It is our belief that an index obtained in the fashion outlined gives a very delicate measure for comparison of these small masses of tissue.

In the tables which include animals that have received transplants of hypophyses from donor rats we have included certain additional data. It was assumed that the average weight of the rats would indicate, at least to some extent the amount of hypophyseal tissue transplanted. It did not seem wise to weigh the individual hypophyses because of the added exposure to possible infections. It is not legitimate to assume that the volume or mass of the hypophysis will bear an accurate ratio to the total weight of the animal but it seemed probable that there would be a sufficiently definite relationship for these

Fig. 5 Photograph of experimental animal No. 40-835 after fixation in Bouin. Note difference in size of ovaries. This was due to extreme distention of bursa on one side X2

weights to be of some significance. We have also included the number of days transpiring between the spaying of the donor rats and the utilization of their hypophyses for transplants. As will be seen in the discussion of the experiments this interval seems to be of considerable importance. In the animals of the earlier experimental series which received injections of commercial extract of placenta the units of estrin present in the placental extract were determined and are listed as total number of rat units received by the donor rat during the course of the experiment.

In Table I (see Figs. 1 and 6) we have presented a series of normal immature mice as a basic measurement for the effects produced in the various experimental groups of animals. In examining Table I it is obvious that the average size of ovaries of normal immature mice as indicated by the index is less than 1. It is unnecessary at this point to describe in detail the histological characteristics of these ovaries as the small immature follicles moderate amount of stroma small hursa and uniform lack of vascular injection are perfectly well known. In Table II (see Figs. 2 and 7) the control experiments for the first series are given. There were fifteen of these animals in which the indices varied from 8 (which is the only animal in the entire group with an index below 1) to 7.2 with an average of 2.9. The size of the ovaries of the control animals have in no single experiment ever been less than the average for the series of normal animals. In other words in all of the animals reported in the control as well as in the experimental group there is definite evidence of hypophyseal effect. Of the control animals only three had an index above four. These animals received hypophyses

clear. In the first place there was a wide variation in the size of the ovaries obtained. The smallest ovary in this series had an index of 2.5 and the largest ovary an index of 19. Such a variation as this would be remarkable in experiments of a more standardized character but the number of factors involved in this experiment was so great that any specific control was almost impossible. Of the factors which we are capable of recognizing some of them have been controlled by the nature of the experiment. It is known for example that castration augments the capacity of the hypophysis to affect the ovary. We are not aware of any investigations which have accurately determined differences in the effect produced following variations in the period between castration and the implantation of the hypophyseal tissue into other animals, however the difference in this group of experiments could not possibly have been due to variations in the time. The largest ovaries were not invariably from mice whose rat donors had been spayed over the longest period of time although there is a slight

tendency toward an increase in size incident to greater length of intervals. Experiments 19, 20, 21, 36 and 37 had 19 day intervals, in these experiments the average index was 9.1. Experiments 28, 29, 30, 31, and 32 all had 15 day intervals in these animals the average index was 3.9. On the other hand the intervals in the remainder of the experiments were 16, 17 or 18 days and the indices in these experiments varied over a wide range (2.5 to 16.7). It would seem legitimate, therefore to conclude that the time between castration and implantation was a factor but that the difference of 2 or 3 days (the maximum difference in these experiments) was insufficient to explain all of the changes noted

The amounts of hypophyseal tissue which were implanted could of course easily be a factor of importance. The hypophyses were not weighed or measured individually but the relation of the weight of the donor rats to the amount of change observed in the recipient mice was noted. We may assume that those animals showing an index above 10 could be considered as a maximum group. There were 4 of these animals showing an average index of 15; the average weight of the donor rats of these animals was 150 grams. In the next group animals showing indices between 7 and 10 the weight of the donor rats was found to be 104 grams. Grouping together all the animals having indices smaller than 7 the average weight was found to be 130 grams. The larger indices were therefore definitely connected with the heavier animals, but the ratio of increase in the weight of the rats is exceedingly small as compared with the ratio of increase in the size of the ovaries of the mice. Furthermore there are many individual exceptions to this average as, for example experiment 19 which had the largest index but which had next to the lowest rat weight (101 grams) as its factor while experiment 46 with an index of 16.7 which is the next largest index in the group had 194 grams as an average weight of rat donors.

The pelvic viscera (with the exception of the ovaries) from these animals were relatively uniform histologically. The uteri and tubes invariably showed marked effects of hypophyseal stimulation. The uterine epithelium was tall showed many mitoses and some tendency toward pseudostratification. The ovaries were more variable in many there were large masses of lutein tissue and many clearly defined corpora. There were also many large follicles, of which a considerable proportion contained blood. An effort was made to correlate the amount of lutein tissue with the number of enlarged follicles, this was not found to be possible in that the ratio of corpora lutea to follicles varied enormously. In some ovaries there was a predominance of corpora lutea, and in others of follicles in general the impression was gained that in individual masses of lutein tissue predominated slightly over the total number of follicles. It was interesting to note however that in none of the ovaries was there an approximately equal increase in follicles and corpora lutea. Either the corpora lutea or the follicles definitely predominated. The blood vessels were markedly injected in every case and in many instances the bursae were markedly distended with fluid (Figs. 3 and 9). In a few instances blood was seen in these distended bursae. Ova

were found in the tubes in considerable numbers and were also seen embedded in masses of lutein tissue and in blood filled follicles. There was no particular correlation found between the size of the ovary and the relative amounts of lutein tissue and follicles. One of the largest ovaries obtained consisted almost entirely of lutein tissue while another of the larger ovaries consisted largely of graafian follicles. This was found to be equally true of those ovaries having smaller indices. After consideration of the results obtained in this group of experiments it does not seem possible to determine any specific liberation of a particular hormone by the hypophysis.

SECOND SERIES OF EXPERIMENTS

When it became obvious from the studies of Leonard Meyer and Hisaw that estrin could not be the factor involved in our experiments it seemed advisable to repeat them in order to determine whether there could have been some error in our procedure or whether the agent causing the changes observed could be some other placental factor. It was considered as more important to obtain a definite separation of the estrus producing hormone than to attempt to isolate all three of Collip's fractions inasmuch as we had no assurance as to which of these (or perhaps some other substance) might be the specific material involved in producing the results already described. It was our object to control our original experiments in a single series of new experiments and to determine in addition if, by this method we could obtain a depression of the ovary stimulating capacity of the hypophysis by estrin similar to that found by Leonard Meyer and Hisaw. These experiments have accomplished both purposes. We found that animals injected with the fraction containing estrin showed less ovary stimulating material in their hypophyses than did control animals and also that the alcoholic extract contained some substance or substances which markedly increases the capacity of the hypophysis to stimulate the ovary.

These experiments have been carried out by one of us (Klingler) and because of certain difficulties, have differed in minor ways from

the original series in the manner of their execution. The donor rats were much larger and the interval between spaying and transplanting was longer than in our original experiments. It is therefore impossible to compare quantitatively the results obtained with those of the earlier group.

All of the extracts used were prepared from fresh human placenta. The method of preparation consisted of repeated extractions in 95 per cent alcohol of finely pulped placenta under reduced pressure at room temperature and in an acid medium. Following each addition of alcohol the material was filtered. Ten volumes of alcohol were used with each extraction the material was then concentrated and all the alcohol removed. The remaining material constituted our crude extract. In preparing the extract containing estrin enough distilled water was added to the crude extract to permit of extraction of the lipoids by ether. The ether soluble material contained the estrin and the remaining extract contained the alcohol soluble material. Further extraction was repeated eight times following which all of the ether was removed under reduced pressure at room temperature.

Sixty adult female rats were spayed and about 3 weeks following the operation were divided into four groups, one group received crude extract one the ether extract containing estrin one the alcohol soluble fraction and one group was used as a control (spayed but not injected). The injections were made subcutaneously twice daily for 6 days at the end of which time the animals were killed and their hypophyses, in the intact state were implanted subcutaneously into infantile female mice. Each mouse received two hypophyses. These were implanted on successive days. The mice were sacrificed on the fourth day and their genital organs examined. The vaginas were open in each case and the uteri were enlarged reddened and injected.

In considering the averages presented in Tables IV, V, VI and VII, one sees that the indices of the entire group of animals included in the second series are larger than those in the first series. This increase is proportionately larger throughout the group and can be clearly demonstrated by comparing the 29

TABLE IV—SECOND SERIES. CONTROLS

average shown in Table II with the 5.9 shown in Table IV and the 7.8 average of Table III F to the 15.8 average of Table VII. In examining these differences we are forced to interpret them as probably resulting from two factors: (1) the greater average weight of the rats used as donors and (2) the longer period of time transpiring between the date of castration and the time at which the rats were sacrificed. In examining these experiments somewhat more in detail, it is interesting to note that the indices of the control series were considerably larger than those of the animals which had received the ether extract (estrin). One might be inclined to presume that the difference of 6 days in the interval between spaying and implantation would be in favor of a smaller size of ovary in the ether extract group. But this should be compensated for at least in part by the slightly greater average weight of the rat donors. We should therefore, be able to assume that the control series is adequate in this connection and that the actual difference in ovary index between 5.9 and 3.7 represents the specific inhibitory effect which was produced upon the anterior hypophysis by the injection of estrin (ether extract). These results are in accord with the findings of Leonard Meyer and Hisaw and Kunde, d'Amour, Gustavson and Carlson.

The ovaries of the control animals contained corpora lutea and follicles in about equal proportions. Some of the follicles were quite large, and a few contained blood. The ovaries of the animals which received the ether ex-

Average		—	1.8	547	33

tract contained a few corpora lutea, a few blood filled follicles and a larger number of follicles which did not contain blood. The latter varied considerably in size some being quite large (Fig. 11). In Table VI we have listed the five animals which received the alcoholic extract. These 5 animals showed an average index of 6.9 with extremes of 3.3 and 9.8. These indices are somewhat larger than those of the controls but not so markedly so as was found in the original series of experiments, with which they cannot however be directly compared. On the other hand when compared with the animals tabulated in Table V (ether extract) it is seen that the average index is almost double which obviously indicates a marked divergence in the effects produced by the ether and alcoholic extracts. The histological changes in the ovaries of the animals which had been given the alcoholic extract consisted of an increase in both corpora lutea and follicles, the latter slightly predominating. The follicles were moderate in size and comparatively regular. A few were filled with blood. The corpora lutea were usually distinctly outlined.

When one considers the five animals included in Table VII which received transplants from rats previously infected with the crude extract it is obvious that a more marked

effect was produced. It is possible that this exaggerated effect was in part due to the slightly increased period between the spaying of the rats and the implantation of the hypophyses. It does not seem probable, however, that this factor could account for the tremendous increase which was found. The differences between the animals injected with the alcoholic and crude extracts must have been due to a failure to remove all of the active substance by our chemical extraction or to some synergistic action of the substances present in the crude extract. Further experiments are under way at the present time with improved methods of extraction to determine which of these possible explanations can be definitely substantiated. These experiments are not, however, needed to establish the primary point of the presence in the placenta of some substance which increases the capacity of the anterior hypophysis to stimulate the ovary.

The ovaries of the animals of the crude extract group differed markedly from all the others of the second series. In 4 of the animals there was a marked predominance of lutein tissue, some of which was in discrete masses, while some was more diffuse and suggested luteinization of unruptured follicles. The fifth animal (No. 20) showed a very large number of follicles which were quite even in size and most of which did not contain blood (Fig. 14). In mouse No. 16 one ovary consisted almost entirely of lutein tissue, while the other had about the same number of follicles as corpora lutea. In animals Nos. 17 and 19 there was a marked predominance of lutein tissue, there being at least three or four times as many corpora as there were follicles. In animal No. 18 the number of corpora lutea was about double that of follicles. In general, therefore, it is clear that the amount of lutein tissue predominated over the number of follicles, except in the one of the five experiments, in which there was an almost complete absence of corpora.

DEDUCTIONS

The experiments outlined have clearly demonstrated that the ovary stimulating properties of the anterior hypophysis can be increased by a placental extract, which probably

contained all three of Collip's fractions, while estrin, one of the components of the crude extract, definitely depresses the hypophysis. It is obvious that the stimulation may be the effect of the anterior pituitary like substance alone or it may be the effect of emmenin and estrin in combination with each other or in combination with the anterior pituitary like substance. There is of course always a possibility that the effect observed was produced by some entirely new substance although this seems unlikely, and it is not at present considered necessary to explain our results. The possibility that there are in the placenta two substances having a diametrically opposite action on the anterior lobe raises the question of a possible balance of these opposing forces under normal conditions. The proper understanding of this balance is full of interesting possibilities.

One must also consider the question of the reaction shown by these experiments in terms of the normal animal. The removal of the ovaries was carried out in order to eliminate the estral cycle and thereby standardize the animals, but it is entirely possible that the presence of these organs intact may furnish some additional mechanism which would modify the effects of these extracts on the hypophysis. One fact which must be remembered is that, in spayed animals, there is a storage of secretion in the hypophysis which does not take place in the normal animal. It is entirely possible that, in our experiments, modification of this mechanism has been produced.

THE FALLACY OF CHEMICAL STERILIZATION OF SURGICAL CATGUT SUTURES

WITH PARTICULAR REFERENCE TO THE USE OF COPPER SALTS, PEPPERMINT OIL, AND MERCURY

RALPH OSKLEY CLOCK M.D., F.A.C.P. NEW YORK

THERE are two principal methods in use today for subjecting catgut sutures to sterilization one is with heat and the other is with chemicals. The primary object of this research work was to determine whether any of the chemical compounds which are on the market or which are otherwise available will exhibit reliable and effective bactericidal properties when used for sterilizing surgical catgut. Efficient germicidal action is claimed or has been demonstrated for many chemical compounds when used for various surgical medical or laboratory purposes. Hence the initial studies in this investigation were confined to the sterilizing action of such compounds on catgut but as the work progressed many other chemical compounds were included in the study.

Contaminated commercial catgut sutures
The chemical method of sterilization has been given, probably a more extensive trial in Germany than elsewhere. And yet Knorr found in his investigations during a 4 year period of bacteriological examination of original packages of catgut obtained from commercial sources or from clinics or from physicians, that at least 80 per cent did not meet the officially established requirements for sterility both pathogenic and non-pathogenic bacteria being found in the sutures. In England, Bulloch purchased and examined bacteriologically 77 sutures manufactured by 8 different makers. Of these, he found 58 sutures or more than 75 per cent to be infected with living bacteria. In this country, Meloney and Chatfield made a 3 year study of the sterility of catgut sutures obtained from surgical clinics or purchased from the open market throughout the country. They found that 12.5 per cent of 174 sutures examined were contaminated with spore bearing bacteria. Sutures from 10 manufacturers yielded no growth, while the products of 7 firms showed bacterial growth ranging from

5 per cent to 67 per cent of specimens tested.

Chemicals previously used
The chemical compounds which have been used in an attempt to destroy the bacteria commonly present in raw catgut are almost legion. In his investigations Macle tried out various strengths of alcohol, glycerol chloroform oil of cloves, oil of eucalyptus phenol lysol formalin, acriflavine, brilliant green crystal violet, biniodide of mercury, perchloride of mercury and silver nitrate but found them lacking in true germicidal properties so far as catgut was concerned. In his review of the disinfecting power of numerous chemicals Bulloch found that phenol, perchloride of mercury, biniodide of mercury, silver compounds, oil of juniper, oil of turpentine, oil of lavender, oil of cadeput, oil of eucalyptus, formalin, picric acid, hypochlorites, chlorine water, bromine, pyoktaniin, methyl blue, eosin, acriflavine, tannic acid, lysol, tellurium sulphur dioxide, alcohols, ether, chloroform, acetone, and benzine were inefficient as sterilizing agents for catgut.

Present researches on chemical sterilization
During the past 2½ years I have made an intensive study of the possibility of effectively sterilizing catgut by means of chemical treatment. In this investigation, I tried out a great many chemical substances including mercuriochrome, mercuriophen, merthiolate, metaphen, potassium mercuric iodide, hexylresorcinol, tribromoresorcinol, orthophenylphenate, ethyl hydrocuprene, tribrometanaphthal, copper cyanide, copper chloride, copper sulphate, copper sulphate plus methylene blue, zinc sulphate, peppermint oil, oil of tea tree (*Melaleuca alternifolia*), hydrogen peroxide, malachite green, pyridium, iodine, iodine plus potassium iodide, myodine, parachlorometacresol, diacetoxymercuriothocresol, parachlorophenol, and chlorthymol ester.

Several thousand sutures treated with various strengths and combinations of these

chemicals, were prepared under various conditions as regards duration of the chemical sterilization treatment, the hydrogen ion concentration and temperature of the solutions etc. the chemical sterilization treatments being applied to catgut ribbons, to raw catgut strings, as well as to catgut artificially infected with a sporulating culture. For controls duplicate lots of the chemically sterilized sutures were subjected to heat sterilization. The finished sutures were tested bacteriologically by the method of Meleney and Chatfield (10).

In searching the literature relating to the sterilization of catgut, I found that rather broad claims are made for copper sulphate and peppermint oil as sterilizing agents for catgut. I also found that these chemical agents are being used for the sterilization of catgut sutures which are claimed to be sterile and which are being used on an extensive scale. Hence it seemed desirable to conduct sufficient experiments with these particular chemicals to check up the claims made for them and to prove or disprove the reliability, practicability and efficiency of these chemicals as sterilizing agents for catgut.

No such claims, however, were found for mercury compounds. But since wide publicity has been given to claims for the germicidal action of some of the mercury compounds now on the market, and in view of the fact that many experiments have been published showing that these compounds exhibit true germicidal action when used for laboratory surgical or medical purposes, I devoted considerable study to the sterilizing action of these mercury compounds on catgut sutures.

Mechanism of disinfection. Although several theories have been advanced to explain the mechanism of disinfection, the investigations of Bancroft and Richter have demonstrated that all types of chemical disinfectants affect bacteria in the same manner—by coagulating the colloids of the cell. The coagulation depends upon the absorption by the colloids of sufficient ions of the chemical substance. Furthermore, they have shown that this coagulation may be of two types: (1) reversible coagulation which inhibits the activity of bacteria but does not kill them (bacteriostatic action or antiseptics), and (2) irreversible coagulation

which is responsible for the death of the bacteria (bactericidal action or disinfection).

Copperized catgut in Germany. At the University of Bonn in Germany von Linden conducted some experiments with catgut sutures by saturating them with copper salts. She claimed that such treatment would completely sterilize the sutures, destroying not only staphylococci but also tetanus spores, and that sutures thus treated would keep sterile for weeks even when left exposed to air and dust. In the Municipal Clinic for Women in Stuttgart, Germany, copperized catgut prepared by the von Linden method has been used for one and one half years by Balach, who reports that the antiseptic action of copperized catgut has been fully demonstrated by exhaustive bacteriological investigation, and that copperized catgut undoubtedly kills not only the pus cocci but also tetanus spores.

Copperized catgut in United States. Early in 1931 while examining sutures of various manufacturers, I found upon chemical analyses that the catgut sutures of three manufacturers in the United States contained appreciable quantities of copper. Bacteriological examination of these sutures by the Meleney and Chatfield (10) method indicated entire absence of growth.

In spite of the fact that von Linden and Balach reported that the bactericidal action of copper salts for catgut had been fully demonstrated, I was not convinced that the American-made copperized catgut sutures which I examined by the Meleney and Chatfield method were in any sense sterile, because I found that their neutralizing solution of 1 per cent sodium thiosulphate and 1 per cent sodium carbonate did not remove the copper salts from the sutures.

Neutralizing fluid for copper. Accordingly various chemical neutralizing solutions were prepared and a study was made of their power of removing copper salts from catgut. Finally after using many chemical solutions and making many tests, I found that the copper salts can be entirely dissolved and removed from the catgut by using a special neutralizing solution consisting of 5 per cent ammonium chloride with $\frac{1}{2}$ per cent ammonium hydroxide. The nature of the chemical reaction involves

the formation of a double salt of ammonia and copper which is water soluble. Repeated chemical analyses of copperized catgut before and after treatment with this neutralizing solution have demonstrated that the catgut sutures can be entirely freed of copper salts. The next step in this research study was thus apparent namely to subject copperized catgut to bacteriological tests in which this special neutralizing solution would be employed to remove the copper salts.

Bacteriological technique. Therefore catgut ribbons made from fresh sheep intestines under ideal sanitary conditions were subjected to the sterilizing action of copper salts after the method recommended by von Linden (6). The copperized catgut ribbons were then made into finished sutures which were tubed in ethyl alcohol. Chemical analyses of these sutures showed appreciable quantities of copper present. In applying bacteriological tests the sutures were first transferred aseptically to tubes of sterile ammonium chloride with ammonium hydroxide and incubated 24 hours. Then they were again aseptically transferred to tubes of this sterile special neutralizing solution and again incubated 24 hours so that the sutures thus received two treatments in the ammonium chloride and ammonium hydroxide solution. Then the procedure adopted by Meleney and Chatfield (10) was followed wherein the sutures were transferred under aseptic technique into sterile distilled water and incubated 24 hours, and then into tubes containing a sterile solution of 1 per cent sodium thiosulphate and 1 per cent sodium carbonate and incubated 24 hours. Finally the sutures were transferred aseptically into tubes of sterile Novy (11) culture medium. Those tubes which were incubated anaerobically were closed with a 'vaspar' seal as used and recommended by Hall. All culture medium tubes were incubated 15 days as recommended by Meleney and Chatfield (10).

Controls. A complete set of controls is essential if the bacteriological test is to prove efficient and reliable. Meleney and Chatfield attempted to surround their standard test with every precaution and the controls which they specified are both important and necessary. However, in addition to the controls

TABLE I—COPPERIZED CATGUT

Prepared by von Linden's process

Series No.	Aerobic tests			Anaerobic tests		
	Tube 1	Tube 2	Tube 3	Tube 4	Tube 5	Tube 6
193	O 24 hrs.	O 24 hrs.	O 24 hrs.	C 24 hrs.	O 24 hrs.	O 24 hrs.
195	O	O	O	C 48 hrs.	C 6 days	O
196	O	O	O	O 13 days	O	O

Explanatory: O indicates bacterial growth, followed by the number of hours or days of the incubation period that elapsed before growth appeared. C means that there was entire absence of growth in the tube at end of 15 days incubation.

Series 193 consisted of control sutures not sterilized by heat nor with any chemicals. Series 195 and 196 were treated with copper salts, treating these sutures bacteriologically, copper salts were best removed from the sutures by means of a special neutralizing fluid of ammonium chloride and ammonia in hydrochloric, and then the sutures were put through the standard Meleney and Chatfield test.

which they described I have demonstrated that other controls are required if the test is to be adequately safeguarded. In applying the standard bacteriological test to the various lots of sutures examined throughout this entire investigation I used the following three additional controls which I think are essential: (1) Aerobic and anaerobic tubes of culture medium were planted with 10 cubic centimeters of each lot of distilled water and incubated 15 days to determine sterility of the water. (2) Aerobic and anaerobic tubes of culture medium were planted with 10 cubic centimeters of each lot of the neutralizing solutions and incubated 15 days to determine sterility of the solutions. (3) Two tubes of culture medium, not planted with catgut but sealed with a layer 2 centimeters thick from every batch made of the 'vaspar' mixture were incubated 15 days to determine sterility of the anaerobic seal.

The bacteriological tests on copperized catgut sutures brought to light both aerobic and anaerobic bacterial growth, the anaerobic growth appearing as late as the thirteenth day, as indicated in Table I.

Artificially infected copperized catgut. The catgut, from which the sutures used in the foregoing experiment were made, represented the usual run of fresh sheep intestines from the abattoir. Therefore, in order definitely to determine the antibacterial action of copper salts, catgut ribbons were artificially infected

TABLE II.—ARTIFICIALLY INFECTED
COPPERIZED CATGUT

Raw catgut artificially infected with sporulating culture and treated with copper salts by von Linden's process

Serm. No.	Aerobic tests			Anaerobic tests		
	Tube 1	Tube 2	Tube 3	Tube 4	Tube 5	Tube 6
9	Q 4 hrs.	Q 4 hrs.	Q 4 hrs.	Q 4 hrs.	Q 4 hrs.	Q 4 hrs.
96	O	O	O	O	O	O
97	O	O	O	3 days	6 days	6 days

Explanation: Q indicates bacterial growth, followed by the number of hours or days of the incubation period that elapsed before growth appeared. O signifies that there was entire absence of growth in the tube at end of 3 days incubation.

Serum 9 consisted of control sutures not sterilized by heat nor with any chemical, but artificially infected with spores.

Serum 96, although artificially infected with spores and treated with copper salts, showed entire absence of growth after test by the standard Meleney and Chatfield method; the neutralizing solution of 1 per cent sodium thiosulphate and sodium carbonate being used.

Serum 97 was treated with the special neutralizing fluid of ammonium chloride and ammonium hydroxide to remove the copper salts, as compared with the standard Meleney and Chatfield bacteriological technique. Anaerobic growth proves that copper salts exert bacteriostatic action and not true germicidal action.

with a sporulating culture of *Bacillus subtilis* and *Bacillus sporogenes*. Some of these ribbons were not treated with any chemical but were immediately made into sutures for controls and tubed in ethyl alcohol. These control sutures were tested by the standard bacteriological method (10). The remaining infected ribbons were treated with copper salts according to von Linden's process and made into finished sutures which were tubed in ethyl alcohol. These artificially infected copperized sutures were divided into two lots, one of which was tested by the standard bacteriological method of Meleney and Chatfield using their neutralizing solution of sodium thiosulphate and sodium carbonate while the other lot was treated with the special neutralizing fluid of sterile ammonium chloride and ammonium hydroxide to remove the copper salts, and then was put through the standard bacteriological test (10). All of the control sutures (artificially infected but not treated with copper salts) promptly showed bacterial growth. All of the artificially infected copperized sutures tested by the standard method (10) and with the standard neutralizing fluid showed entire absence of growth but the lot of artificially infected copperized sutures that was treated with the

special neutralizing fluid and then was put through the standard bacteriological technique (10) showed *anaerobic bacterial growth* as indicated in Table II.

This experiment demonstrates that *copper salts do not sterilize catgut* but merely arrest bacterial growth through bacteriostatic action. It also proves that sodium thiosulphate and sodium carbonate will not remove copper salts from catgut and that if this solution be used as the sole neutralizing fluid falsely negative results will be obtained.

Commercial copperized catgut sutures. From the open market, I again purchased catgut sutures of the three American manufacturers whose products on previous analyses had been shown to contain copper salts. When analyzed chemically the product of manufacturer A was found to contain 0.34 per cent copper, that of manufacturer B contained 0.75 per cent copper while the sutures of manufacturer C contained 1.23 per cent copper. The tubing fluids used by these manufacturers consisted of alcohol denatured with a mercury compound. After removing the copper salts under aseptic technique with sterile ammonium chloride and ammonium hydroxide the sutures were subjected to the standard bacteriological test of Meleney and Chatfield. One hundred and fifty-six copperized catgut sutures from these three manufacturers were tested and 42 of them were found to contain living bacteria of the aerobic and anaerobic types. Thus approximately 27 per cent of these copperized catgut sutures were non-sterile, as indicated in Table III.

Von Linden's copperized catgut was purchased from manufacturer D in Germany and when analyzed chemically the sutures were found to contain approximately 3 per cent copper. After aseptically removing the copper salts by means of the ammonium chloride and ammonium hydroxide solution, the standard bacteriological test was applied. The results showed that 19 out of 36 (52 per cent) of the sutures contained living bacteria (see Table IV). These results confirm those obtained by Weichardt in the Erlangen Hygienic Institute as reported by Mehnert. Professor Weichardt believes that copperized catgut should be rejected because it lacks the

All sutures were treated with the special neutralizing fluid of ammonium chloride and ammonium hydroxide to remove copper salts as a preliminary step to the standard Miley and Chetfield bacteriological method.

important quality of sterility and my views coincide with his on this subject

Bacteriostatic action of copper Vignati and Schaebel have shown that copper salts act on bacteria by coagulating the bacterial colloids an action similar to that on serum colloids. These investigators have demonstrated that copper salts, when added to a broth culture of *Bacillus coli*, constitute a mechanical obstacle to bacterial activity in that the chemical compound isolates the bacteria from their surroundings and deprives them of nutritional support, thus preventing their multiplication. They have also shown that the bacteria may be reactivated by means of a neutralizing solution capable of re-dissolving the copper coagulum, which is thus proved to be directly reversible.

From a study of the results of my researches on copperized catgut described in this paper,

it is evident that when catgut sutures are treated with copper salts an arrested development of the bacteria within the catgut is brought about through the bacteriostatic action of the copper. Apparently, the copper salts act on the bacterial colloids in such a manner that, even in the presence of a suitable culture medium, the bacteria are deprived of their nutritional support. It is equally evident from my experiments that the removal of the copper salts from the catgut by means of an effective neutralizing fluid consisting of ammonium chloride and ammonium hydroxide, reactivates the bacteria, so that, when nutritional support is provided in the form of a proper culture medium bacterial growth occurs.

Reaction of tissues to copperized catgut While the above bacteriological tests on copperized catgut were in progress some plain

TABLE IV.—COPPERIZED CATGUT SUTURES

Made in Germany

D Lot 2	G 48 hrs	O 48 hrs	O 48 hrs	O	O	O	O 5 days	O 21 days	O	O	O	O

Explanation: G indicates bacterial growth, followed by the number of hours' or days' incubation that elapsed before growth appeared. O means no growth observed in the tube at end of 9 days' incubation.

All sutures were treated with the special neutralizing fluid of ammonium chloride and ammonium hydroxide to remove copper salts before being tested by the standard McNeely and Chittenden bacteriological method.

(untreated) catgut sutures sterilized by heat and some of a similar size treated with copper salts after the method of von Landen and also subjected to heat sterilization were embedded in animal tissues for the purpose of determining the relative degree of irritation produced in the tissues by the plain and by the copperized sutures. Both kinds of sutures were prepared from the same batch of raw catgut in order to assure uniform raw material.

Each of these two kinds of sutures was woven through the serosal layer of a rabbit's stomach under aseptic technique. Four rabbits were used and they were sacrificed at 5 day intervals. After noting the gross pathological appearance of the removed stomachs, illustrative pieces of tissue containing the suture were placed in 10 per cent formaldehyde and histological sections made and mounted on microscopic slides. Simple haematoxylin eosin stain as well as the fibrous tissue differential stain of van Gieson, was used.

A study of the histological appearance of the tissues after the sutures had been embedded for 5 days 10 days 15 days, and 20 days, showed that the copperized catgut was less readily absorbed than the plain untreated catgut sutures. Also the copperized sutures were definitely more irritating as indicated by the greater cellular response which they produced as compared to the plain untreated sutures.

Peppermint oil catgut sutures in England. A very novel and ingenious method adopted for the chemical sterilization of catgut sutures was reported by Porritt. In this method, the

raw catgut is first soaked 6 hours in a solution of sodium bichromate phenol and glycerin then dried and placed in hermetically closed containers filled with peppermint oil in ethyl alcohol (1 to 10). These containers are immersed in a water bath at 60 degrees C for 2 hours on 2 successive days. The sutures are then removed from the containers and preserved in 1 to 20 phenol in ethyl alcohol.

In order to demonstrate the efficiency of his method, Porritt artificially infected some raw catgut with *Bacillus subtilis*, *Bacillus sporogenes*, *Bacillus tetanus* and *Bacillus welchii*. The infected sutures were then put through his peppermint oil process for chemical sterilization and the peppermint oil and chromic acid were removed by distillation with ether and water in a sterile Soxhlet apparatus. For controls, another lot of catgut was similarly infected and then subjected to the distillation process. The sterilization process with peppermint oil being omitted. Both lots were then subjected to bacteriological tests (technique not described). He reports that all culture tubes containing the peppermint oil treated sutures showed entire absence of bacterial growth while the tubes of the control sutures all contained a heavy growth of bacteria corresponding to the species used for artificially infecting the catgut.

Bacteriological tests of peppermint oil catgut. Owing to the fact that Porritt's peppermint oil catgut sutures are made and used exclusively in a British hospital they are not for sale in the open market in England. However I endeavored to secure some of these sutures direct from Mr. Porritt and to obtain

details of his bacteriological tests but without success. Therefore, in order to test the value of peppermint oil as a sterilizing agent catgut sutures were prepared under ideal sanitary conditions from the ordinary run of fresh sheep intestines at the abattoir and sterilized by Porritt's complete peppermint oil process as outlined. The sutures were then tested bacteriologically by the standard method of Meleney and Chatfield. Five lots of controls were also tested as follows: (a) In order to remove the possibility of all chemicals used in the peppermint oil process from acting as sterilizing agents raw catgut was subjected to the peppermint oil process and then all chemicals were extracted with ether and water in a sterile Soxhlet apparatus; the catgut being placed in sterile thimbles. (b) To exclude phenol in the tubing fluid as the possible sterilizing agent some raw catgut not subjected to the peppermint oil or other treatment was stored for 72 hours in 1.20 phenol in ethyl alcohol in hermetically sealed tubes. (c) To rule out the peppermint oil as the possible sterilizing agent raw catgut, after being subjected to Porritt's peppermint oil process was extracted with ether to remove the peppermint oil, the catgut sutures being placed in sterile thimbles and no tubing fluid used. (d) To exclude sodium bichromate as a possible sterilizing agent raw catgut was soaked 6 hours in Porritt's solution of sodium bichromate, phenol, and glycine but no further treatment was given; the sutures being transferred aseptically from this solution to the bacteriological testing fluids. (e) As an additional control raw catgut strings (untreated) were also tested.

The bacteriological tests were applied in accordance with the technique previously referred to as the standard method of Meleney and Chatfield. All culture tubes (aerobic as well as anaerobic) containing the peppermint oil treated sutures as well as those containing the controls (a, b, c, d, and e) showed bacterial growth within 48 hours, thereby demonstrating that catgut sutures prepared by the peppermint oil method of Porritt are non-sterile. This experiment was repeated with another lot of raw catgut, but the results were the same (see Table V).

Series 100, 110, 120, 121, 122 and 108 are control lot and correspond to controls (a), (b), (c), (d), and (e) described in the text.

Series 108 and series 118 comprised sutures prepared from two different lots of raw catgut. Both series were sterilized by Porritt's process. Sutures in all of these series were tested by the standard Meleney and Chatfield method.

Artificially infected peppermint oil catgut

While these results demonstrated that the peppermint oil process will not sterilize even the ordinary run of raw catgut and the method is therefore inefficient and unsafe because the peppermint oil sutures contain living bacteria yet it seemed advisable to prove conclusively the presence or absence of any germicidal properties of peppermint oil for catgut by treating some artificially infected catgut by the Porritt method. Accordingly catgut ribbons were infected with a sporulating culture of *Bacillus subtilis* and *Bacillus sporogenes*. Then the ribbons were made into finished sutures which were divided into two lots: one of which was subjected to Porritt's peppermint oil process while the other lot was left untreated for control. The results of bacteriological tests on the two lots are shown in Table VI and these results prove beyond all question that Porritt's method of chemically sterilizing catgut with peppermint oil is unsafe.

Mercury compounds for sterilizing catgut A large number of experiments was carried out by subjecting catgut ribbons, raw catgut strings, as well as artificially infected catgut, to chemical sterilization with the various mer-

Series 24 consisted of control sutures artificially infected but not treated with peppermint oil.

Series 25, after being artificially infected, was put through Porritt's process with peppermint oil.

All sutures were tested by the standard Meleney and Chatfield method.

cury compounds previously mentioned. The results of bacteriological tests of such chemically sterilized sutures showed however that none of these mercury compounds will effectively sterilize catgut.

During the year 1931 in connection with my study of mercury compounds, I purchased in the open market, at intervals of a few months, several lots of catgut sutures of American manufacturer E. Chemical analyses always revealed an appreciable amount of a mercury compound in the sutures and my bacteriological examinations of this manufacturer's sutures showed the presence of living bacteria in at least 3 specimens from every batch of twelve sutures which I tested by the Meleney and Chatfield method. These results were in conformity with those which I obtained when testing the experimental lots of sutures sterilized chemically with the various mercury compounds. However chemical analyses of this manufacturer's sutures purchased early in 1932 showed them to be heavily impregnated with a mercury compound and when such sutures were examined bacteriologically by the standard test of Meleney and Chatfield, entire absence of bacterial growth was indicated.

Upon further investigation I found that the amount of the mercury compound present in the sutures purchased in 1932 was so large (3.5 per cent) that the neutralizing fluid of 1 per cent sodium thiosulphate and 1 per cent sodium carbonate used in the standard Meleney and Chatfield test would not remove all

of the mercury compound from the sutures. Accordingly a 5 per cent solution of sodium thiosulphate was tried for this purpose but it was found that even this strength would not remove all of the mercury compound from the sutures. Further research demonstrated that this could be attained by means of a neutralizing fluid consisting of 10 per cent solution of sodium thiosulphate. Therefore, as the next logical procedure, some sutures of manufacturer E purchased in 1932 were tested bacteriologically by first transferring them aseptically to and incubating them in, a sterile neutralizing solution of 10 per cent sodium thiosulphate for 24 hours and then by putting them through the standard Meleney and Chatfield technique. The results of these tests showed the presence of living bacteria in the sutures.

Two additional lots of sutures of manufacturer E were purchased. One lot consisted of plain catgut sutures while the other lot was chromic catgut. Chemical analyses of these sutures revealed the presence of a large amount of a mercury compound (mercuric iodide). Twelve sutures of each lot were examined bacteriologically by the standard Meleney and Chatfield method, and the results indicated entire absence of bacterial growth (see Table VII). Twelve other sutures of these same lots and bearing the same batch numbers were first transferred under aseptic conditions to and incubated for 24 hours in, the neutralizing solution of 10 per cent sodium thiosulphate. Then these sutures were put through the standard bacteriological technique of Meleney and Chatfield, and all twelve sutures of one lot (plain) and eight sutures of the other lot (chromic) were found to contain living bacteria (see Table VIII). Hence it is evident that the mercury compound present in such large amount in these sutures exerted a bacteriostatic action, thereby arresting development of the bacteria within the catgut. Likewise, it is apparent from these experiments that removal of all of the mercury compound from the sutures, by means of a neutralizing solution of 10 per cent sodium thiosulphate, reactivates the bacteria which are thus enabled to grow in the culture medium.

TABLE VII—MERCURIALIZED CATGUT SUTURES

Tested by standard Meleney and Chatfield method

Manufacturer	Aerobic tests						Anaerobic tests					
	Tube 1	Tube 2	Tube 3	Tube 4	Tube 5	Tube 6	Tube 7	Tube 8	Tube 9	Tube 10	Tube 11	Tube 12
E Lot 1	0	0	0	0	0	0	0	0	0	0	0	0
E Lot 2	0	0	0	0	0	0	0	0	0	0	0	0

Explanatory: 0 means entire absence of growth in the tube at end of 14 days incubation.

Sutures comprising Lot 1 were plain catgut, while those of Lot 2 were chlorinated catgut.

Chemical analyses showed that these sutures contained 3½ per cent of mercury also that all of the soluble mercury was not removed from the sutures by the neutralizing solution of 10 per cent sodium thiosulphate and 1 per cent sodium bicarbonate used as part of the standard Meleney and Chatfield method.

TABLE VIII—MERCURIALIZED CATGUT SUTURES

Tested by standard Meleney and Chatfield method, but a special neutralizing solution of 10 per cent sodium thiosulphate was used as a preliminary step

Manufacturer	Aerobic tests						Anaerobic tests					
	Tube 1	Tube 2	Tube 3	Tube 4	Tube 5	Tube 6	Tube 7	Tube 8	Tube 9	Tube 10	Tube 11	Tube 12
E Lot 1	4 days	4 days	4 days	5 days	11 days	0	7 days	9 days	1 days	0	13 days	0
E Lot 2	0	0	0	0	0	0	0	0	0	0	0	0

Explanatory: 0 indicates bacterial growth followed by the number of hours or days incubation that elapsed before growth appeared. 0 means entire absence of growth in the tube at end of 14 days incubation.

Sutures comprising Lot 1 were plain catgut, while those of Lot 2 were chlorinated catgut.

These sutures were taken from the same lots and bore the same batch numbers as the sutures used for the tests shown in Table VII. Before being put through the standard Meleney and Chatfield technique these sutures were transferred aseptically to tubes of sterile 10 per cent sodium thiosulphate and incubated for 4 hours to remove the large amount of mercury (3½ per cent).

These results serve to emphasize the fact that falsely negative findings may follow the use of the standard Meleney and Chatfield test unless a close check up is always made first, by subjecting some of the sutures under examination to careful chemical analyses to determine the nature and quantity of any chemical compound that may be present, and second by using in connection with the bacteriological tests a suitable neutralizing fluid which will dissolve and remove whatever chemical compound is found to be present.

In order to detect the presence of bacteria in catgut which has been subjected to the chemical action of such large amounts of a mercury compound as are being used by American manufacturer E, the use of 10 per cent sodium thiosulphate for a neutralizing solution is recommended. This solution should be used as a preliminary step to the standard bacteriological technique of Meleney and Chatfield, so that the 10 per cent solution of sodium thiosulphate will be removed from the sutures by the distilled water which con-

stitutes the first step of the standard Meleney and Chatfield method and thus will not be carried over into the culture medium where it might inhibit bacterial growth.

Other chemical compounds for sterilizing catgut. The sterilizing action of each of the other chemical compounds included in this study was systematically investigated. A careful study was made of the effect of wide variations of the several factors involved in the application of the chemical to the catgut, such for example, as the strength of the solutions, the duration of the chemical sterilizing treatment (time of contact) the hydrogen ion concentration and temperature of the solutions, buffering of solutions, as well as combinations of the chemicals. Moreover, these studies included the effect of the sterilizing action of the chemical compounds on catgut ribbons, raw catgut strings, and artificially infected catgut.

Before attempting to evaluate the possible merits of any of the chemicals under investigation, a large number of sutures prepared in

various ways was subjected to the sterilizing action of the chemical under a wide variety of conditions and the sutures were then tested bacteriologically by the standard method of Meleney and Chatfield.

In some of the early studies of this investigation the bacteriological results were encouraging. Thus, the chemical compounds which seemed to give promise of exerting a true sterilizing action on catgut were metaphen, copper sulphate diacetoxymercurothochresol, and iodine plus potassium iodide. However if the bacteriological results indicated that some particular chemical apparently exhibited effective germicidal properties on some lots of catgut ribbons or of raw catgut strings, the experiment was repeated under precisely the same conditions several additional lots of catgut being used with the view of confirming the results. Invariably the bacteriological results of these confirming experiments failed to establish the reliability and effectiveness of the chemical as a sterilizing agent. But if the results still appeared to hold out promise of ultimate success and therefore to warrant still further experiments, artificially infected catgut was also subjected to the sterilizing treatment with that particular chemical compound.

Although several of the chemical compounds included in this study have been reported by various authors to possess germicidal properties for various surgical, medical or laboratory purposes, *none of them proved to be efficient and reliable agents for the chemical sterilization of catgut.* Owing to the large number of tests that were applied the tabulated results obtained with each of the various chemical compounds studied would occupy a very large amount of valuable space. Hence, it has been necessary to omit tables showing results with chemicals other than copper sulphate, peppermint oil and mercuric oxide. The reason for including detailed and tabulated results obtained with these three chemicals must be apparent from the foregoing information relating to them.

Chemical sterilization inefficient. Thus far the chemical compounds which have been tried out in an attempt uniformly and effectively to destroy the bacteria commonly pres-

ent in raw catgut have given disappointing and unreliable results. Most chemicals have had an especially weak action upon the spore-forming bacteria which are often found in the innermost portions of the gut.

During the course of this investigation, the sterilizing action of each of the 27 chemical compounds studied was applied to a large number of lots of catgut sutures prepared from fresh sheep intestines under ideal sanitary conditions, also to many lots of artificially infected catgut. None of the chemicals was found to have reliable or uniform sterilizing action on catgut and in no case did all lots of sutures, sterilized with any one of the chemicals or a combination of the chemicals prove to be entirely free from living bacteria. Therefore the net results indicate the fallacy of the chemical method of sterilizing catgut, so far as the chemical compounds included in this study are concerned.

This research work involved bacteriological studies of 334 experimental lots of catgut comprising several thousand sutures, together with 154 commercial lots embracing 1134 catgut sutures. The results of this investigation have proved conclusively that *chemical sterilization of surgical catgut as employed at present is inefficient and unreliable.* Hence it becomes evident that chemically sterilized catgut sutures are unsafe because their sterility is uncertain unless of course some chemical not included in this study or which may be developed in the future proves to be an effective sterilizing agent for catgut.

Heat sterilization effective and reliable. Unlike chemical disinfection the efficiency of sterilization of catgut sutures by heat does not depend upon the absorption of ions. On the contrary heat of an effective degree penetrates all parts of the cell colloid of any bacteria that may be within the catgut, and thus devitalizes the essential matter of the bacterial cell.

In my studies of the chemical sterilization of surgical catgut each experiment was controlled by subjecting to heat sterilization a duplicate lot of catgut sutures that had been treated with the particular chemical being studied. In every instance, the heat-sterilized sutures came through the bacteriological tests

with entire absence of bacterial growth, thus proving that *heat sterilization properly controlled is the only safe and positive method for sterilizing surgical catgut sutures*. Moreover there was no impairment of tensile strength as a result of the heat treatment thus showing that with sufficient care effective heat sterilization can be applied without altering the physical properties of the catgut.

SUMMARY

In this investigation which extended over a period of 2½ years several thousand catgut sutures were prepared from 334 lots of catgut. Twenty seven different chemical compounds were used for treating these various lots of catgut under a wide variety of conditions in an attempt to bring about chemical sterilization, the various chemical treatments having been applied to catgut ribbons to raw catgut strings, as well as to artificially infected catgut.

The chemical compounds used in this research study included mercurochrome mercuriphen merthiolate metaphen potassium mercuric iodide hexylresorcinol tribrommercurinol orthophenylphenate ethylhydroxy prene tribrombetanaphthal copper cyanide copper chloride copper sulphate copper sulphate plus methylene blue zinc sulphate peppermint oil oil of tea tree (*Melaleuca alternifolia*) hydrogen peroxide malachite green pyridium iodine iodine plus potassium iodide myodine parachlorometacresol diacet oxymercurothiocresol parachlorophenol and chlorthymol ester.

In applying the chemical sterilization processes the effect of wide variations in the several factors involved was studied including the strength of the chemical solutions the duration of the chemical sterilizing treatment, the hydrogen ion concentration and temperature of the solutions buffering of solutions, and combinations of the chemicals. Duplicates of each lot of catgut that received chemical sterilization treatment were also subjected to heat sterilization as a control.

In addition to the large number of experimental lots of catgut which were subjected to the sterilizing action of the various chemical compounds before mentioned, this investiga-

tion also included a study of the sterility of 154 commercial lots purchased from the open market and comprising 1134 catgut sutures.

Throughout these experiments the standard bacteriological test, devised and proposed by Meleney and Chatfield was used for determining the sterility of catgut, but 3 additional controls were used and are recommended as essential for safeguarding the reliability and efficiency of the test.

The results of my experiments with copperized catgut sutures herein described have demonstrated that copper salts applied to catgut by the von Linden method do not effectively sterilize catgut. These findings confirm those of Weichardt as reported by Mehnert (8). Moreover, my copperized catgut experiments have shown that copper salts exert a bacteriostatic action on the bacteria in catgut, for when the copper is removed with a suitable neutralizing fluid the bacteria become reactivated.

It was found that the 1 per cent solution of sodium thiosulphate and sodium carbonate used by Meleney and Chatfield in their standard test for neutralizing mercury compounds and iodine will not remove copper salts from catgut sutures. A solution consisting of 5 per cent ammonium chloride and ½ per cent ammonium hydroxide was found to be an effective neutralizing agent for dissolving and removing copper salts from catgut.

Copperized catgut sutures embedded in animal tissues were less readily absorbed and were definitely more irritating than plain (untreated) catgut sutures.

Chemical analyses of catgut sutures of three American manufacturers and of one German manufacturer revealed appreciable quantities of copper. Bacteriological examinations showed the presence of living bacteria in 42 of 156 (approximately 27 per cent) of the copperized sutures of the 3 American manufacturers, and in 19 of 36 (52 per cent) of the copperized sutures of German make (von Linden process).

Peppermint oil catgut sutures were demonstrated by repeated bacteriological tests to be 100 per cent non sterile. This method of sterilizing catgut, recommended by Porritt, not only fails to sterilize artificially infected cat-

gut but even the ordinary run of raw catgut made from fresh sheep intestines and processed under ideal sanitary conditions

Chemical analyses of catgut sutures marketed in 1932 by an American manufacturer revealed a large amount of a mercury compound, and when such sutures were examined bacteriologically by the standard test of Meleney and Chatfield entire absence of bacterial growth was indicated. The large amount (3.5 per cent) of the mercury compound could not be removed from the sutures by the neutralizing solution of 1 per cent sodium thiosulphate and sodium carbonate used in the Meleney and Chatfield test but it was found that a neutralizing fluid of 10 per cent sodium thiosulphate effectively removes the mercury compound from the sutures. When sutures of this manufacturer were tested bacteriologically by first incubating them for 24 hours in a sterile 10 per cent solution of sodium thiosulphate and then by putting them through the standard Meleney and Chatfield technique the results showed the presence of living bacteria in the sutures.

Bacteriological tests, applied to commercial catgut sutures containing a large amount of a mercury compound have shown that arrested development of bacteria within the catgut is brought about through the bacteriostatic action of the mercury compound. These tests have also proved that removal of the mercury compound from the sutures by means of a suitable neutralizing fluid reactivates the bacteria which then are able to grow in the culture medium.

None of the 27 chemical compounds studied in this investigation was found to have reliable or uniform sterilizing action on catgut for in no case did all lots of sutures sterilized with any one of the chemicals or a combination of the chemicals, prove to be entirely free from living bacteria. However every one of the duplicate lots of sutures which were subjected to heat sterilization showed entire absence of bacterial growth.

CONCLUSIONS

1. When applying the standard bacteriological test of Meleney and Chatfield for determining the sterility of surgical catgut

sutures, the details of the chemical treatment to which they have been subjected must be known or else careful qualitative and quantitative chemical analyses of some of the sutures must first be made to ascertain the nature and amount of the chemical compound used to impregnate the sutures.

2. A suitable neutralizing fluid must be devised and used to dissolve and remove the particular chemical substance found in the catgut sutures before applying the standard bacteriological test.

3. The necessity of incubating commercial catgut sutures for at least 15 days is clearly indicated by the results of bacteriological tests shown in Tables III and VIII wherein the greatest number of growths occurred on the thirteenth day and some growths appeared even as late as the fifteenth day (Table III). This confirms the findings of Meleney and Chatfield who reported the appearance of the largest number of growths on the thirteenth day and who recommended an incubation period of 15 days as a margin of safety.

4. When used with the three additional and essential controls herein described, and when used in conjunction with suitable neutralizing fluids for dissolving and removing the chemical compound with which the sutures may be impregnated the standard bacteriological test proposed by Meleney and Chatfield seems to be an efficient and reliable test for the sterility of surgical catgut sutures.

5. The so called chemical sterilization of surgical catgut by any method yet devised is inefficient and unreliable.

6. Carefully controlled heat sterilization is the only uniformly reliable and positive method of sterilizing surgical catgut sutures.

EXPERIMENTAL SHOCK. THE EFFECT OF BLEEDING AFTER REDUCTION OF THE BLOOD PRESSURE BY VARIOUS METHODS¹

N. W. ROOMIE, M.D. CHICAGO, W. S. KEITH, M.D. TORONTO, CANADA, and
D. B. PHLEMISTER, M.D. F.A.C.S., CHICAGO
From the Department of Surgery, the University of Chicago

In clinical surgery the effects of trauma or an operation are estimable by observations on the pulse, blood pressure, respiration, reflexes, color of skin and mucous membranes and occasionally by other factors. Of these the blood pressure is commonly held the most important single index and is frequently the only finding given much consideration. But since the blood pressure is maintained by several factors (ventricular contraction, peripheral resistance, blood volume and viscosity), and may be reduced by alteration of any of these, the significance of a lowered pressure is very variable. It is therefore not a reliable guide to the condition of the patient without regard for the cause of its depression and for the other means of evaluating its importance. Thus a low pressure produced by hemorrhage usually indicates a serious state of the circulation in which further loss of blood or an operation is badly tolerated but an equally low pressure occurring as a result of spinal anesthesia may have no such significance, and an operation may be completed without undue risk. Hadenfeldt states from a study of a large series of spinal anesthetics that the effect of loss of blood is no more serious under spinal than under general anesthesia, Burch, Harrison and Blalock, however, reached an opposite conclusion from animal experiments. It has been observed in

this and other clinics that the blood pressure may fall considerably with a concurrent slowing of the pulse during upper abdominal operations such as cholecystectomy or gastric resection without apparent cause and rapidly return to normal levels upon closure of the abdomen with no noticeable after-effects. Hadenfeldt assumes this effect to be due to traction on the vagus nerve below the diaphragm with reflex cardiac inhibition.

In an endeavor to test experimentally the value of blood pressure readings as an index of the condition of the circulation and to evaluate the seriousness of the blood pressure fall of spinal anesthesia, the blood pressure was lowered in dogs to 'shock levels' by nine different methods and the effect of bleeding the animals to death was studied. Certain observations made in the course of these experiments have a bearing on the general problem of the mechanism of traumatic shock as to whether a histamine like toxin is liberated from the damaged tissues (Cannon, 5, and Cannon and Bayliss, 6), or whether there is sufficient local loss of fluid to account for the fall of blood pressure (Blalock, 2, and Parsons and Phlemister, 16). In addition it was attempted in several animals without success to reduplicate the fall of blood pressure which results in man after upper abdominal operations.

¹This work was aided by a grant from the Douglas Smith Foundation for Medical Research of the University of Chicago.

EXPERIMENTAL METHODS

The blood pressure was reduced in a series of 50 dogs to levels usually between 50 and 70 millimeters of mercury by the following methods: hyperventilation, anaphylactic shock, histamine administration, spinal cord section, spinal anesthesia, trauma to a limb, hemorrhage, plasmapheresis, and intestinal manipulation. The animals were bled to death in most experiments approximately 1 hour after the initiation of the procedure, and the amount of blood obtainable was measured. Anesthesia was by ether or sodium-barbital. Blood counts were made in 37 cases before and after the depression of the blood pressure. Bleeding was by a large carotid cannula, the animal being left in the horizontal position and the cannula kept free of clots, the bleeding volume thus obtained is presumed to be an approximate index of the circulating blood volume and will be described in the remainder of this paper as a percent age of the calculated blood volume (one-thirtieth of the body weight). The experiments and the results obtained will be described in groups according to the method used to depress the blood pressure.

1. CONTROL SERIES

Twenty additional dogs were merely anesthetized, 10 with ether and 10 with sodium-barbital, and bled at the end of an hour. The results are contained in Table I and indicate that while there is a considerable individual variation of the bleeding volume there is no significant difference in this respect between the two anesthetic agents. The individual variations are probably due to (1) mechanical errors in bleeding, (2) individual characteristics, notably the proportion of fat to the other tissues of the animal, and (3) differences in the water content of the tissues and the alimentary tract. The percentages of the calculated blood volume obtained from the normal animals varied from 34 to 85 per cent, and averaged 58.6 per cent.

2. HYPERVENTILATION

Henderson (9) as early as 1905 described the depression of the blood pressure in acapnia, and offered this phenomenon as an initiating agent of surgical shock. Recent evidence (McDowell) indicates that acapnia has a dual effect on the circulation, a central vasodilatation which usually predominates, and a local constriction of smaller and more peripheral vessels.

a. Hyperventilation by intratracheal insufflation. Six dogs anesthetized by sodium barbital were each hyperventilated by connection of a cannula in the trachea to two Palmer respiration pumps, arranged so as alternately to pump in and suck out the same volume of air and operated at approximately 140 revolutions per minute. Due to temperature changes, this method of artificial respiration was found to result in slightly increased intrapulmonary pressure; this effect was minimized by connecting a T-tube in the system to permit communication with the atmospheric air. A rapid fall of blood pressure

occurred in each case, and at the end of approximately 1 hour while the artificial respiration was continued the amounts bled were from 31 to 41.5 per cent of the calculated blood volume, the average being 35.7 per cent. Blood counts showed no constant or marked change.

b. Hyperventilation by external alternating pressure. From observations made on the dogs of Series 2a and other animals, it was concluded that in hyperventilation by the intratracheal method there are certain factors capable of causing a blood pressure fall independent of the degree of acapnia, viz. mechanical impairment of the pulmonary circulation, as noted by Janeway and Ewing, and reflex vasodilatation from increased intrapulmonary and intrabronchial pressure (Johnson and Luckhardt). Therefore a somewhat more physiological method of artificial hyperrespiration was devised (17) in which the animal was enclosed in a metal cylinder with its head projecting in the manner of the Drinker respirator and alternately positive and negative air pressure applied to the exterior of the body by connection to two Palmer pumps operated synchronously at approximately 115 revolutions per minute. When this method was applied to 3 dogs anesthetized with sodium barbital, the blood pressure fell slightly immediately, recovered to nearly the normal level, then slowly fell to levels of from 53 to 69 millimeters of mercury. The bleeding volumes at these levels, while the artificial respiration was continued, were from 50 to 67 per cent of the calculated blood volume, averaging 56.3 per cent. This average is relatively much higher than that obtained in lowered pressures from intratracheal insufflation, even when the difference in terminal pressures is considered, this is a further indication that in the intratracheal method there is actual obstruction to the pulmonary circulation, while in the external pressure method the effects are more purely due to acapnia with secondary vasodilatation. For this reason, although the results of both series of experiments are included to Table II only those of series 2b will be considered in the discussion to follow. It must also be noted that the external alternations of pressure would minimize any stagnation of blood in the veins, as has been suggested may occur in acapnia (Henderson, 10) but in these experiments a considerable fall of pressure occurred in the absence of such stagnation.

3. ANAPHYLAXIS

A fall of blood pressure occurs in dogs during "anaphylactic shock," the mechanism of which is not entirely clear but is presumably the same as with the analogous "histamine shock," i.e., by direct action on the capillaries (Soliman).

Eleven dogs were sensitized to pig's blood, and when under ether anesthesia small amounts of the same blood were injected intravenously anaphylactic shock of a satisfactory degree developed in 5 animals. In these the blood pressure fell rapidly to low levels, with a tendency to recover in some cases.

TABLE I—BLEEDING VOLUMES OF NORMAL DOGS ANESTHETIZED FOR ONE HOUR

Average	51.8	Average	62.4

Average of 20 dogs 51.6 per cent of the calculated blood volume

*Fat dog. †Very fat dog

The time interval was necessarily short in this series and the severity of the reaction was very variable. On bleeding from 29 to 63 per cent of the calculated blood volume was obtained the average being 51 per cent (Table III). Erythrocyte counts showed no constant change.

4 HISTAMINE ADMINISTRATION

The effects of histamine on the circulation are complex. In a few species it raises the blood pressure while in dogs and most other animals it produces an extensive fall of blood pressure apparently by direct action on the capillaries (Dale and Richards), the condition being similar to surgical shock (Mellanby).

Histamine (ergamin acid phosphate) was given in aqueous solution by a continuous intravenous drip in 5 dogs, and subcutaneously in a dog No. 487. By both methods the blood pressure slowly fell to the desired levels. Four of the animals were anesthetized with ether, 2 with sodium barbital. The amounts bled were from 36 to 66 per cent of the calculated blood volume and the average was 50.5 per cent (Table IV). Blood counts were made in 5 cases. In 3 there was no significant change. In 2 there was a slight increase in the red cells.

5 SPINAL CORD SECTION

The spinal cord was cut after preliminary laminectomy in the region of the first thoracic segment, in 6 dogs anesthetized with ether. There was usually little bleeding during the laminectomy, and that incidental to cutting the cord was minimized by immediately packing the wound. The procedure thus represents the combination of a small operation with spinal cord section. The blood pressure reaction to

the section was somewhat variable but there was typically an immediate rise due to transient stimulation of the vasoconstrictor nerves, then a gradual fall in 25 to 30 minutes to levels of from 52 to 68 millimeters of mercury due to interruption of the vasomotor pathways. The amounts bled were from 41 to 51 per cent of the calculated blood volume averaging 48 per cent (Table V). There was a slight decrease in the erythrocyte count in four of five cases.

6 HIGH SPINAL ANESTHESIA

A 3 per cent solution of procaine in physiological salt solution was injected intrathecally in the upper lumbar region in 4 dogs after laminectomy and in 2 (Nos. 385, 417) without laminectomy. All were under light ether anesthesia. Sufficient procaine was slowly injected to produce relaxation of the entire chest wall and in some a slight slowing of the respirations. The blood pressure fell gradually and continuously as the anesthesia spread upward presumably by interference with conduction of vasomotor impulses in the efferent spinal nerves. From 38 to 55 per cent of the calculated blood volume was obtained, the average being 44 per cent (Table VI). No blood counts were made in this series.

7 TRAUMA TO AN EXTREMITY

Cannon and Bayliss (6) concluded that the fall of blood pressure after trauma to an extremity was due to the liberation of a toxic histamine like substance

from the injured tissues, with generalized vasodilatation and increased capillary permeability. Later observations by Blalock (3) and Phenister and Parsons (16) have shown that there is sufficient local loss of fluid into the traumatized area to account entirely for the blood pressure fall.

In the present experiments, trauma was applied to one or both hind limbs of 4 dogs by many blows with a padded hammer; sodium barbital was the anesthetic in all cases. The blood pressure usually fell but slightly with the first hammering, and more sharply with the successive hammerings; this is similar to the effect of repeated bleedings, as will be described. Blood counts showed a diminution in all cases. The bleeding volumes were from 33 to 56.5 per cent of the calculated blood volume, averaging 34.6 per cent (Table VII).

8. HEMORRHAGE

In 7 dogs small amounts of blood were repeatedly withdrawn from a carotid artery; 5 of the animals were anesthetized with sodium barbital and 4 with ether. Recovery of the blood pressure occurred sharply and nearly completely after the first few withdrawals, slowly and less completely after the later bleedings. Erythrocyte counts showed a diminution in all cases. From 19 to 35 per cent of the calculated blood volume was obtainable, the average being 24.9 per cent, after from 33 to 64 per cent of the calculated blood volume had been removed by bleeding (see Table VIII). The average

Average			59	5	48

total amount bled during the experiment and at the terminal bleeding was 70.4 per cent of the calculated blood volume. This increase over the amount obtainable at one continuous bleeding is presumably due to the absorption of fluid from the tissues during the slow bleeding.

9. PLASMAPHERESIS

The reduction of the blood pressure was attempted in several animals by the withdrawal of a quantity of blood after heparin administration, the plasma being removed by centrifugation, and replacement of the cells; these experiments were unsuccessful, the time interval being very long and death frequently occurred in the later stages before the cells could be replaced, as noted by Bayliss. Therefore the following plan was adopted, 2 animals being used. Blood from dog 1 was drawn, centrifuged, and its plasma decanted, then dog 2 was bled, and cells from dog 1 immediately replaced in proportionate quantity. This process was repeated two or three times, until the blood pressure remained at a shock level (after from 34 to 53 per cent of the calculated blood volume had been removed as plasma) at which time the animals were bled to death. By this technique the time required was reduced to an average interval of 82 minutes; no reactions attributable to foreign protein were observed. The blood was, of course, concentrated by the procedure. In 5 cases the amounts bled were from 15.5 to 27 per cent of the calculated blood volume, and the average was 19.7 per cent. The average total volume of fluid removed during the experiment and at the terminal bleeding was 59.1 per cent of the calculated blood volume; this figure is lower than the average total volume removed during the hemorrhage experiments and probably indicates that the greater loss of plasma proteins and correspondingly lower osmotic pressure of the blood in the plasmapheresis experiments permitted less withdrawal of the tissue fluids into the blood stream.

10. MANIPULATION OF THE INTESTINES

Experiments on intestinal manipulation in dogs by Phenister and Parsons indicate that the intestinal volume is not increased during the procedure.

and Blalock (3) found that a plasma like exudation occurs from the surface of the intestine in adequate amounts to explain the fall of blood pressure.

In 6 dogs of the present series the intestines were brought out through an abdominal incision and severely massaged with the fingers. 5 were anesthetized with ether, 1 with sodium barbital. There was little or no external hemorrhage although moderate ecchymosis occurred in the area manipulated, and a considerable weeping from the surface of the bowel was observed as described by Blalock. The fall of blood pressure was very gradual and could not be much accelerated by more vigorous massage hence the time interval was increased to an average of 104 minutes. The bleeding volumes were from 12 to 21 per cent of the calculated blood volume, the average being 18 per cent. The erythrocyte counts were irregularly increased indicating a concentration of the blood in all cases.

II UPPER ABDOMINAL MANIPULATIONS

The fall of blood pressure which occasionally occurs during operations in the upper abdomen in man, and which is usually accompanied by a slowing of the pulse, is presumably a reflex phenomenon and may be related to the cardio-inhibitory reflex from the upper abdomen of certain species and easily demonstrable in the frog (Luckhardt).

Several unsuccessful attempts were made to reproduce this effect in dogs, by traction upon and resection of the gall bladder and stomach and by stimulation electrically of the gastric vagi below the diaphragm. No satisfactory fall of blood pressure of adequate duration for study could be obtained in the dogs tested.

DISCUSSION OF RESULTS OF EXPERIMENTS

The results of all types of experiments are summarized in Table VI. It will be noted that the average bleeding volume for the normal anesthetized dogs (series 1) was 58.6 per cent of the calculated blood volume, and that the bleeding volumes after reduction of the blood pressure fall into two groups according

to whether there is a slight or a marked reduction of the bleeding volume.

The first group includes the following procedures: hyperventilation, anaphylaxis, histamine administration, spinal cord section and spinal anesthesia. In these (series 2b to 6, inclusive), there was obtained from 44 to 56 per cent of the calculated blood volume figures but slightly diminished from the normal, and the two lowest figures of the group were in the conditions of spinal anesthesia and spinal cord section in which a small operation was included in the procedure. The mechanism of the blood pressure depression in these experiments was by arteriolar or capillary dilatation or both, and the maintenance of nearly normal bleeding volumes indicates that the circulating blood volume is not greatly diminished.

In the conditions of trauma to an extremity and hemorrhage (series 7 and 8) there was obtainable at similar blood pressure levels a much smaller volume of blood, approximately 25 per cent of the calculated blood volume, and an even greater reduction of the bleeding

volume occurred after lowering the blood pressure by plasmapheresis, and by manipulation of the intestines (series 9 and 10) approximately 20 per cent of the calculated blood volume being obtained. These 4 series constitute a second group of experiments in which a considerable reduction of the bleeding volume occurred as a result of actual loss of circulating blood volume. The erythrocyte counts made in this group although somewhat irregular indicated a dilution of the blood in extremity trauma and hemorrhage and a concentration of the blood in plasmapheresis and intestinal manipulation; the corresponding differences in viscosity may account for the differences in the bleeding volumes i.e. the more concentrated blood of plasmapheresis and intestinal manipulation may permit a smaller circulating blood volume to maintain a given blood pressure than the diluted blood of trauma and hemorrhage. As has already been noted the blood pressure behaved similarly in its reaction to repeated withdrawals of blood and to repeated trauma. In situations of an extremity there being little

effect at first and an increasing effect later in the procedure. The coincidence of the bleeding volumes of this group of experiments and the other findings support the opinion that the fall of blood pressure in experimental trauma and intestinal manipulation is due to local loss of fluid as blood or blood and plasma into the damaged tissues and as plasma exudation from the intestine.

By comparing the bleeding volumes of the two groups of experiments it is apparent that the animals of the first group were in much better condition by virtue of their nearly normal circulating blood volume, to withstand hemorrhage or an operation than the animals of the second group in which the bleeding volume was markedly reduced during the time period considered in the present studies. Therefore a lowered blood pressure of such duration is not as serious a condition when produced by vasodilatation or "bleeding into the vessels," as some writers have implied, as when the pressure is lowered to similar levels by actual loss of fluid from the circulation, as in experimental trauma, intestinal manipulation and hemorrhage.

While these experimental procedures do not exactly simulate surgical shock in man the findings apply to the problem of its mechanism at least in part. Therefore, it is thought that in clinical shock (1) the hidden loss of fluid for instance locally into the tissues in trauma, may be more important as an etiological agent than toxemia or other suggested

factors, (2) the blood pressure is not in itself an adequate guide as to the condition of the patient, as it may be nearly normal in the presence of a seriously embarrassed circulation or vice versa, and (3) further hemorrhage or an operation is more dangerous when the blood pressure is lowered by hemorrhage or by trauma, in which blood or plasma is lost, than by spinal anesthesia or other vasodilator mechanism in which there occurs the so called "bleeding into the vessels." And clinical experience warrants the inclusion in the vasodilator group the depression of the blood pressure which occurs during upper abdominal operations with a concurrent slowing of the pulse. Spinal anesthesia was demonstrated to have but slight influence on the bleeding volume and presumably the circulating blood volume and is therefore to be considered but slightly more dangerous than ether or barbitol anesthesia.

SUMMARY

The state of the circulation in 50 anesthetized dogs after lowering the blood pressures to "shock levels" by 9 different methods was studied by comparing the average bleeding volumes of each series with the average amount of blood obtained by bleeding usually after the lapse of 1 hour. The average bleeding volume of 20 normal anesthetized dogs was 58.6 per cent of the calculated blood volume. The experiments fell into two groups according to whether or not a considerable diminution of the bleeding volume occurred at the reduced pressure.

In the first group of experiments the average bleeding volume was 56.2 per cent of the calculated blood volume when the blood pressure was lowered by hyperventilation, 51 per cent when by anaphylaxis, 50.5 per cent when by histamine administration, 48 per cent after spinal cord section, and 44 per cent with high spinal anesthesia. The average bleeding volume for the entire first group was 49.9 per cent of the calculated blood volume, a slight depression from the normal average. In the conditions enumerated the mechanism of depression of the blood pressure was by dilatation of the arterioles or capillaries or both. It was concluded that in these conditions, dur-

ing the time interval studied, there was little or no diminution of the circulating blood volume at the reduced pressure, and it would seem that the lowered blood pressure of spinal anesthesia did not appreciably increase the dangers of operation or hemorrhage, since the blood volume remained at or near normal.

In the second group of experiments the average bleeding volume was found to be 24.9 per cent of the calculated blood volume after the blood pressure had been lowered by hemorrhage, 24.6 per cent when by trauma to an extremity, 19.7 per cent after plasmapheresis and 18 per cent after intestinal manipulation. The average for the entire group was 21.8 per cent of the calculated blood volume and was thus very considerably reduced from the normal. In the case of hemorrhage and plasmapheresis there was direct and obvious loss of fluid from the blood stream, and a similar loss presumably occurred in the conditions of trauma, where there was local loss of blood and plasma into the injured area and in intestinal manipulation where the fluid appeared to be lost principally as plasma. It was concluded that in this second group of experiments the circulating blood volume was much more seriously diminished at similar blood pressure levels than in the first group, and that the animals were correspondingly less able to withstand hemorrhage or an operative procedure. The similarity of the bleeding volumes was further evidence that the mechanisms of lowering the blood pressure are identical in trauma to an extremity and hemorrhage, and in intestinal manipulation and plasmapheresis.

CONCLUSIONS

1. In states of circulatory depression the blood pressure is an inadequate index of the seriousness of the condition.

2. The circulating blood volume is not seriously diminished, and hence operation or loss of blood is well tolerated, in conditions of lowered blood pressure due to vasodilator mechanisms, such as spinal anesthesia, and including presumably the fall of blood pressure which sometimes occurs in upper abdominal operations in man with a concurrent slowing of the pulse.

3 The circulating blood volume is markedly diminished when the blood pressure is reduced by hemorrhage experimental extremity trauma or experimental intestinal manipulation. In these conditions the animal is much less able to withstand further hemorrhage or an operation than if the blood pressure be depressed to a similar degree by a vasodilator mechanism.

4 The effects of experimental trauma and intestinal manipulation on the blood pressure are due to local loss of fluid rather than to a toxemia.

PASSIVE ANTITOXIC IMMUNITY IN STREPTOCOCCAL INFECTION OF THE PERITONEUM

ROBERT S. SMITH, B.A., B.Sc. (Oxon.), St. Louis, Missouri
 from the Sir William Dunn School of Pathology, University of Oxford, Oxford, England

ALTHOUGH antibacterial sera have been discredited as agents for the prevention and treatment of streptococcal infections in the reports of McLeod, Novak and others, antitoxic sera are at present enjoying considerable popularity. Warnick, Lousos and Becker, Caessler and Lash have prepared antitoxic sera using puerperal strains of streptococci and describe the favorable effect of such sera in severe infections in the puerperium. Furthermore in accordance with the concept of the unity of the streptococcal toxins, which is supported by the experimental work of Paraf, Eagles, Smith, Parish and Okell, Moriawaki and Wadsworth, antitoxides specific for the toxins of scarlet fever streptococci are being applied in the treatment of a variety of other streptococcal diseases.

Schabatai has used scarlatinal antitoxin with success in the treatment of erysipelas. Sanderson, Capon and MacWilliam have found that the administration of scarlatinal antitoxin produces a favorable effect in streptococcal septicaemias. Boente and Killian have described the successful use of scarlatinal antitoxin in the treatment of a number of different diseases having a streptococcal etiology including puerperal fever, acute angina, lung abscess, mastitis and cellulitis. Baird and Cruickshank have reported a reduction in the incidence of puerperal infection by prophylactic administration of scarlatinal antitoxin. Few reports however of specific treatment of streptococcal infection of the peritoneum using antitoxic sera are to be found in the literature. Wilkie obtained encouraging results with the therapeutic administration of convalescent serum in streptococcal infections of the peritoneal cavity and Duncan has suggested that it may be advisable to give scarlatinal antitoxin in the treatment of primary streptococcal peritonitis in children.

The present work was undertaken to determine experimentally the potentialities of

antitoxin in the treatment of a streptococcal infection of the abdominal cavity and to investigate the bodily reactions associated with passive antitoxic immunity in such a disease. The experiments were limited to an investigation of the infective process produced by a Dochez strain of streptococcus isolated originally from a case of scarlet fever. The organism was only moderately virulent but an active producer of toxin. Filtrates of 72 hour tryptic digest broth cultures giving a positive skin test in a susceptible individual in a dilution of 1 to 1000 and killing rabbits of 1800 to 2000 grams weight within 24 hours when injected intravenously in doses of 10 cubic centimeters.¹

EXPERIMENTAL

Prophylactic effect of antitoxin. Ten rabbits that had received subcutaneous injections of 2 cubic centimeters of antitoxin 16 hours previously with ten normal controls were given an intraperitoneal injection of 10 cubic centimeters of 16 hour tryptic digest broth culture of the streptococcus. The animals were studied in pairs, one protected by antitoxin and one unprotected and were selected according to breed, sex and weight. Of these rabbits all of the unprotected died in 6 to 20 hours, all of the protected animals survived and were killed at intervals after recovery from the acute infection. Three of the surviving animals were killed after 1 week, 1 after 2 weeks, 1 after 3 weeks and 5 were allowed to live for 30 days. In this experiment changes in weight, temperature, peritoneal fluid and blood picture including total white blood cell count, white blood cell differential count, red blood cell count, haemoglobin percentage and blood culture were studied, particular attention being paid to the sequence of events in the blood and peritoneal fluid during the first 6 hours.

The antitoxin used in all experiments was that produced by Burroughs-Wellcome Company and known as concentrated streptococcus antitoxin (scarlatina) globulin.

Animal dead in twenty hours

As a control upon the specificity of the protection conferred by the streptococcus anti-toxin rabbits that had received prophylactic injections of concentrated diphtheria anti-toxin-globulins¹ were inoculated intraperitoneally with the standard dose of streptococcus culture. These animals succumbed to the infection in the same time as the normal controls.

After the injection of culture the unprotected animals gave symptoms of a greater toxæmia than the passively immunized group and were usually prostrated by a diarrhoea during their short period of resistance to the infection. All of the animals receiving anti-toxin showed an increase in temperature within 6 hours, to a level above 104 degrees F. In the unprotected controls on the other hand an inhibition of the temperature reaction was noted 8 of these animals showing a temperature below 100 degrees F. 6 hours after the injection of culture. Examinations of the leucocytes of the peritoneal fluid in film preparations demonstrated that the mobilization

of polymorphonuclear leucocytes in the abdominal cavity during the acute phase of the infection was more pronounced in the immunized animals than in the control group and phagocytosis of the infecting organisms was more effective in the animals receiving anti-toxin. In the protected animals the phase of recovery from the infection was characterized by a diminution in the numbers of the polymorphonuclear cells in the peritoneal fluid with a restoration of the normal predominance of the mononuclear leucocytes (Table I).

In the blood, an early leucocytosis, followed by a marked leucopenia, was characteristic of the reaction to the inoculation with streptococcal culture in both the immunized animals and the controls. The animals receiving anti-toxin showed however a greater leucocytosis in the first 20 minutes and the succeeding leucopenia was less pronounced in this group.

Fig. 4. Photomicrograph of omentum of protected animal 7 hours after inoculation. There is a marked polymorphonuclear reaction, and streptococci are within phagocytes. \times 580.

The averages of the white blood cell counts per cubic millimeter of blood after 20 minutes and 6 hours in the two groups of animals were as follows: 20 minutes—immunized animals 23,135 controls 15,665; 6 hours—immunized animals 6,090 controls 4,922. The leucopenia was continued until death in the group of unprotected rabbits. In the protected group, however, a second and more prolonged leucocytosis was commonly observed after 48 hours.

Differential and absolute counts of the white blood cells showed that the polymorphonuclear leucocytes were of the chief importance in the leucocytic reaction to the acute infection (Table II). Depression of the polymorphonuclear response was noted in the group of unprotected animals.

Blood cultures indicated that a more severe bacteremia occurred in the unprotected rabbits. Six hours after infection all of these animals gave a positive blood culture, while only one test was positive in the protected group after the same interval.

A moderate anemia and a decrease in weight were characteristic of the first week following infection in the animals protected by antitoxin. After 30 days the hemoglobin percentage and red blood cell count had returned to their normal values in most animals,

and compensation had usually been made for the initial weight loss. Two of the rabbits protected by antitoxin developed within the first week an arthritis affecting the joints of the hind legs. These inflammations persisted until the animals were killed after 2 and 3 weeks, respectively.

Postmortem, the normal controls showed the histological changes characteristic of an acutely fatal infection. The peritoneal fluid and the membranes of the abdominal cavity showed a failure of the leucocytic reaction with proliferation of the streptococci, and cultures of the heart blood and peritoneal fluid were uniformly positive for the organism. In the anterior mediastinal lymph nodes, numerous streptococci were observed in the lymph sinuses. Organisms were also readily demonstrated in sections of the liver and spleen of animals dying later than 10 hours after injection with culture. Foci of necrosis were observed in the liver. Acute congestion of the lungs, spleen and kidneys was noted, and hemorrhages were found in the heart muscle. Evidences of a severe drain upon the leukoblastic tissues were observed in sections of the bone marrow, with degenerative changes in the hematopoietic cells. The picture presented in this group of animals was that of a toxic depression of the vital systems of the

body, especially that concerned with leucocytic reaction to pathogenic bacteria, allowing a generalized invasion of the body from the original focus of infection in the abdomen.

In the protected animals killed after their survival of the acute phase of the infection a marked hyperplasia of the lymphoid tissues throughout the body was observed with a pronounced myeloblastic reaction in the bone marrow. A marked development of myeloid tissue was also noted in the spleen in animals killed 1 week after infection. In addition to the 2 cases of arthritis already noted a sub-acute pericarditis was found in one animal at autopsy. In the group of immunized animals, recovery from the infection of the abdominal cavity was apparently correlated with an intense reaction of the leucoblastic tissues of the body. The residual chronic foci of infection found in these animals in spite of the prophylactic administration of antitoxin, undoubtedly had their origin in a blood stream infection associated with the acute peritonitis.

Comparison of immunized animals with normal controls in same phase of acute infection. In order to compare the histological changes in the protected and unprotected animals during the same phase of the acute infection 4 rabbits receiving prophylactic injections of streptococcus antitoxin with 4 normal controls, were killed 7 hours after having been inoculated intraperitoneally with 10 cubic centimeters of standard culture and complete autopsies were performed.

Total counts of the cells of the peritoneal exudates in these animals post mortem demonstrated that the leucocytic response in the immunized rabbits was quantitatively greater than that in the controls. A greater quantity of exudate was present in the abdominal cavity of the immunized animals, and when total counts were made of the peritoneal leucocytes the average number of cells in the protected group was found to be 8,500 per cubic millimeter of fluid as compared with an average count of 625 per cubic millimeter in the controls. The predominance of polymorphonuclear cells among the leucocytes of the peritoneal fluid was also more pronounced in the protected rabbits than in the controls. The average of the polymorphonuclear percentages in the immunized rabbits was 96 as compared with a corresponding average of 67 in the control group.

A greater mobilization of leucocytes in the tissues of the omentum with more marked phagocytosis of the infecting organisms, was noted in the immunized animals and preparations of the diaphragmatic lymphatics and anterior mediastinal lymph nodes also gave evidence of a more effective leucocytic reaction to the bacterial invasion in this group. Centers of proliferation of the streptococci were seen in the omentum, diaphragmatic lymphatics, and anterior mediastinal lymph nodes in the normal controls.

Therapeutic effect of antitoxin. Six rabbits were given an intravenous injection of 2.5

cubic centimeters of concentrated streptococcus antitoxin 3 hours after having received 10 cubic centimeters of culture intraperitoneally. The time interval between the inoculation with culture and the injection with immune serum was of sufficient length to make the test one of considerable severity. A significant prolongation of life resulted however in all instances but one following the administration of the specific antiserum.

As compared with an acutely fatal infection of 10 hours duration in 3 control rabbits receiving therapeutic injections of diphtheria antitoxin the disease in the animals given specific therapy was chronic in nature. The rapid course of the infection was unaffected in one animal which was given streptococcus antitoxin 3 others died after 80 to 128 hours 2 of this group made a complete recovery. In the overwhelming infection of these experiments therapeutic injection of streptococcus antitoxin was commonly followed by an increase in temperature increased phagocytosis of the streptococci by the leucocytes of the peritoneal exudate and a rise in the blood leucocyte count. The pathological changes noted at autopsy in animals dying after several days of resistance to the infection were those of a severe septicemia.

Control experiments. The changes in temperature blood picture and peritoneal fluid

observed in experiments in which intraperitoneal injections were made of simple digest broth and of the filtrate of a 16 hour streptococcal culture showed that the inoculum of the reported experiments contained toxic substances apart from the bacteria themselves. The toxicity of these substances was not great however and the irritating properties of the products of bacterial metabolism present in cultures after 16 hours of incubation may be considered to constitute a constant factor in the experimental infections.

SUMMARY AND CONCLUSIONS

1. In the present work it has been found that a high degree of immunity to intraperitoneal inoculation with a toxigenic moderately virulent scarlatinal streptococcus can be produced by the administration of specific antitoxin. From the experimental evidence this immunity seems to depend upon the neutralization by the antibody of toxin produced by the infecting organism *in vivo* and the resistance of the body to the infection which is facilitated by the elimination of the toxic factor is manifested by an increase in temperature a local and general mobilization of leucocytes and the removal of the invading bacteria from the peritoneal cavity and blood stream by phagocytic cells. The immunity conferred by the prophylactic administration

of antitoxin enables the animal body to survive the acute phase of a disease which is rapidly fatal for the unprotected control but even this high degree of antitoxic immunity is not sufficient to prevent the development in a certain percentage of cases of later chronic infections. Therapeutic use of antitoxin has definite limitations as indicated by the experimental results. The administration of the antitoxin after the onset of the infection appears to enhance the defensive powers of the body however and may be followed by a completely successful resistance to the bacterial invasion and recovery.

2 The findings in these experiments substantiate the view of Downie, that toxin aids the establishment of streptococcal infection by inhibiting phagocytosis. As neutralizing toxin and favoring the leucocytic reaction to the bacterial invasion antitoxin appears to possess distinct potentialities for the control of infections of the abdominal cavity caused by toxigenic streptococci.

3 The present work indicates that the highest degree of passive antitoxic immunity in streptococcal infection of the peritoneum is produced by prophylactic administration of the serum. In the therapeutic use of antitoxin it would seem, however that the administration of the serum very early in the disease might confer a protection comparable to that produced by prophylactic infection. Early therapeutic administration of antitoxin should restrict tissue invasion to a minimum, and

thereby limit the possibility of infections of a focal nature developing as complications.

This report represents a summary of experiments performed by the writer as a Rhodes Scholar elected from the Washington University School of Medicine (1930-1932). The writer is greatly indebted to Professor George Dreyer, F.R.S., for his advice and material support in carrying out these experiments. He also wishes to express here his gratitude for very stimulating criticisms and suggestions that have been received from Dr. A. W. Downie of the University of Manchester, Professor J. W. McLeod of the University of Leeds, Dr. G. H. Eagles of the Lister Institute, Professor D. F. Cappel of the University of St. Andrews, Professor D. P. D. White of the University of Edinburgh, and Dr. T. B. Heaton, Dr. R. L. Volkmann, and Dr. H. M. Carleton of the University of Oxford.

THE TREATMENT OF LATE ACUTE INTESTINAL OBSTRUCTION

RECENT EXPERIMENTAL AND CLINICAL STUDIES¹

ROBERT ELMAN, M.D., St. Louis, Missouri

From the Department of Surgery, Washington University Medical School and Barnes and St. Louis City Hospitals

IN this discussion of acute intestinal obstruction I shall be concerned almost entirely with the late and therefore serious cases which of course offer the greatest problem in treatment. The patient seen early generally does very well and such cases carry a low mortality, even after a radical operation for relief. It is obvious therefore that the education of the public as well as the profession in early diagnosis would reduce the tremendously high mortality. Moreover if the use of purgatives for abdominal pain were generally avoided I am sure the treatment would also be easier and more favorable. Unfortunately we cannot wait until such education becomes effective. The mortality (15) of late intestinal obstruction is still around 60 per cent, as high as it ever was in spite of the great amount of research on the subject. In 1926 in the mortality statistics of this country over 10,000 deaths were recorded from intestinal obstruction. We are confronted constantly with patients in the later stages of this disease. It is the consideration of such patients to which I wish to direct attention.

A woman, for example, some weeks or months after a simple hysterectomy suddenly develops abdominal cramps which go away as quickly as they come only to return in a few minutes or after an hour or two. The patient thinks it is an ordinary belly ache and takes a dose of salts has a moderate bowel movement, but the pain continues and she notices that her abdomen is becoming more distended. She then takes some castor oil but the pain becomes worse and she vomits. The distention becomes more marked and the pain perhaps diminishes in severity. The vomitus may become foul in odor. A doctor is called, she is rushed in the hospital, operated upon and dies or she may not call a doctor and die without benefit of a diagnosis.

What was the cause of death? We are accustomed to explain the symptoms of prostration and weakness which develop before death as due to a toxemia in spite of the fact that we have no absolute evidence that this is

in fact true. During the past few years a series of new observations have been made as to the cause of death which have contributed greatly to our understanding and treatment of certain of these cases. Some of this work has been done in the Surgical Laboratory at the Washington University Medical School and in Barnes and other hospitals associated with it. In order to present these observations more clearly it will be of advantage for purposes of discussion to divide intestinal obstruction into two groups: (1) High obstruction that is at the pylorus from a scarred duodenal ulcer or hypertrophic stenosis or carcinoma or at the terminal duodenum from adhesions some times developing after gastro-enterostomy, congenital bands, etc. (2) Low obstruction which is by far the most frequent and is located commonly at the ileocecal valve or beyond, due to adhesions following operation especially after a ruptured appendix, a congenital band, strangulated hernia, carcinoma, etc. The pathology of each will be first discussed and treatment will be taken up later. Strangulation will be considered separately later on. Intestinal obstruction complicated by peritoneal infection as well as the so called paralytic ileus will not be included in the scope of the paper.

HIGH OBSTRUCTION

Persistent vomiting is a prominent symptom of high obstruction and comes on almost immediately after ingestion of food or liquid. The vomitus contains not only the fluid swallowed but gastric and pancreatic juice as well. These secretions often pour out in absence of any food intake and sometimes several liters may accumulate in a dilated stomach with very little actual vomiting. Distention is usually limited to the upper abdomen. Increasing weakness and prostration rapidly develop with the absence usually of much pain. The pulse grows weaker and faster the skin becomes

¹Read June 22, 1927, at joint meeting of the Syracuse Academy of Medicine, the Onondago Medical Society and Section N of the American Association for the Advancement of Science at Syracuse, New York.

drawn and dry, the sensorium depressed and coma and death supervene in a few days, if the patient is untreated and if the obstruction is complete. Because these changes occur more quickly and death more rapidly than is the case in low obstruction it was for a long time assumed that the toxæmia was more severe the higher the occlusion.

We now know that in high obstruction the factor of toxæmia is of little or no significance. It may be of some interest to trace briefly the development of this advance. Hartwell and Hogue of New York in 1913 were the first to escape from the toxæmia theory by adducing evidence that death resulted from loss of water by vomiting. They made no studies of the blood. Haden and Orr in 1923 reported low blood chlorides but for a long time still clung to the idea of a toxin which combined with the chloride ion. They later gave up this idea. Our work began in 1926 when with Dr. McCaughan I first reported that total loss of pancreatic juice was rapidly fatal (7). The symptoms were not unlike those seen after high intestinal obstruction. There was vomiting, weakness, fast pulse, prostration, shock and death usually within 7 days. We were unable to explain this rapid death until with Dr. Hartmann intensive studies of the blood chemistry were made (5). We found briefly that the experimental animals with pancreatic fistula showed the same changes as babies with severe diarrhea, patients with duodenal or pancreatic fistula or high intestinal obstruction. These changes were those of anhydremia, i.e. a high protein content often up to 11 per cent from a normal of 7 per cent, a low water content indicating marked concentration of blood as shown also by a high hematocrit reading, a loss of base and chlorides, acidosis and finally a rise of non protein nitrogen. These changes can be explained on a purely chemical basis from the loss of water and salts in the drained pancreatic juice or in the vomitus in high obstruction. In other words, constant vomiting removes from the body not only water but the important salts of the gastric and pancreatic secretions which are normally reabsorbed to some extent from the intestine. The high non protein nitrogen is probably due to

the anuria since the blood becomes too thick to pass the kidney capillaries.

Practical proof of the idea that we were dealing with purely chemical and physical changes was shown by the striking improvement in symptoms upon replacing the lost water and salts by means of intravenous injections of Ringer's solution which contains the common salts that are found in the gastric and pancreatic secretions. Animals moribund from loss of pancreatic juice could be brought back to life by the introduction of sufficient combined solution, a modified Ringer's solution which I will describe later. In subsequent experiments (6) with high intestinal obstruction and fistula we were also able to cure the so called toxic symptoms and prolong life by replacing the essential water and salts, lost in the vomitus, by parenteral injections.

These observations, with which most of you are by now undoubtedly familiar are of course not characteristic of high obstruction. They are really due to loss of gastro-intestinal secretions from the inevitable concomitant vomiting. They apply equally to the profuse vomiting in infants from pyelitis, or other infections in protracted hysterical vomiting where no gastro-intestinal lesion is present in severe diarrhea where the secretions pass through so quickly that no fluid is reabsorbed and in high intestinal fistulae. Indeed if one minimizes vomiting in a high intestinal obstruction by withholding all food by mouth symptoms are delayed and life is likewise prolonged.

Thus one can see that practically everything we know about the so called toxæmia of high intestinal obstruction can now be explained on purely physicochemical grounds. The loss of water and salts, in absence of absorption drains the blood of water, base, chlorides, bicarbonate etc. it becomes too concentrated for the peripheral circulation, local outlying acidosis (17) undoubtedly occurs, kidney function stops and death results. Replacing the lost water and salts dilutes the blood back to normal peripheral circulation is re-established, kidney function begins, and the interchange between blood and tissues returns to normal.

LOW OBSTRUCTION

It was hoped for a time that this fruitful development of research in high obstruction could be used in cases of low obstruction. These hopes were only partially realized. We have seen that the key to our understanding of the pathology of high obstruction was the loss of gastro intestinal secretions. In contrast to this, very slight loss usually occurs in low obstruction since vomiting is not apt to be a very prominent symptom. Indeed Dr Hartmann and I have investigated the blood chemistry in ileocaecal as compared with duodenal obstructions in some detail (6). The blood changes in low occlusion were relatively slight and certainly not sufficient to explain death. This was true of both patients and experimental animals. Moreover the administration of parenteral solutions influenced the symptoms but slightly and did not delay the inevitable lethal outcome.

There are other important differences. In high obstruction the course of the patient is progressively downward and can be correlated with the increasing dehydration of the blood. In low obstruction the so called "toxic" symptoms may not appear for days even in the presence of distention which may be severe. Pain may also have diminished. The pulse rate may be normal and the blood pressure unchanged. Yet not infrequently sudden shock and death occur often within a few hours. At autopsy there is no perforation or other obvious cause for death. We have seen this phenomenon occur similarly in experiments on dogs. Pediatricians see it in infants with so called intestinal intoxication.

I have several times noted that suddenly dilating an enormously dilated bowel above a long standing obstruction may lead to a rapidly fatal outcome. This has also been the experience of others. Heusser and Schar cite the case of a 3 year old child who 4 months after operation for a ruptured appendix and while apparently well suddenly developed acute obstruction. At operation a single band was found occluding the distal ileum which was cut and the obstructed contents seen to pass into the healthy bowel but 10 hours later the child was dead. The authors produced closed loops in rabbits. The distended

bowel was opened in 24 hours whereupon the animals died within 10 minutes. We have seen the same phenomenon occur several times. The sudden access of obstructed fluid into normal bowel has been assumed to be the cause of sudden death but we have no evidence that any of the toxic material present in the fluid is absorbed from the normal intestinal mucosa. More likely it seems to me, is the sudden release of tension in the distended bowel.

The key therefore to the pathology of low obstruction in my opinion is first the inevitable distention which it produces, second the effect of sudden release of tension. These two facts I shall consider in some detail.

Distention. Distention is an early and important symptom and sign and is due to the attempts on the part of the body to overcome the occlusion. Wave after wave of peristalsis, associated with the characteristic cramping pain tries to break through the occlusion and succeeds only in dilating the intestine more and more to make room for the intestinal contents brought down and which cannot get through. The stagnation leads to increased bacterial action and the resulting gas produces an added force distending the gut still more. This leads to a vicious circle, for the increased pressure, at least up to a certain point stimulates the secretory activity of the mucosa (16). Mucus as well as digestive fluids therefore are added to the volume of intestinal contents dammed back from the impassable lumen and the wall stretches still more. Let us examine such an obstructed distended bowel. The contents are partly gas but mostly liquid, foul smelling and very toxic, that is if injected intravenously into an experimental animal. This single fact has dominated much of the research on intestinal obstruction and in my opinion, has belated the true state of affairs. We now know that normal intestinal contents are toxic. They contain active trypsin, peptones, phenols, amines and other substances besides gas bacilli and other bacteria which will kill on intravenous injection. To be sure the obstructed contents contain a much higher concentration of these toxic materials and bacteria. But one can introduce a liter of such fluid into the normal gastro-intestinal tract

and nothing serious occurs. On the other hand there is enough poison and bacteria in a few cubic centimeters of some normal intestinal contents to kill when injected into the circulation. So we see that it is not so much a question of demonstrating a poison in the mucosa, the wall, or the contents of the intestine, but rather of demonstrating whether it gets out how it gets out and, of course, if it does, what its chemical or bacterial nature is. Attempts have been made. It is true to demonstrate the absorption of a toxin. Sugito and Schofield are the only workers who were able to kill mice with portal blood from obstructed dogs. But their results were not constant and were obtained with difficulty. We have had the same experience. Dr. Cole and I (1) have studied the thoracic duct lymph, portal blood and systemic blood from dogs sick of low intestinal obstruction by injecting the material into guinea pigs which are rather susceptible to toxic amoeba. We have not convinced ourselves as yet that toxin enters the circulation in abnormal amounts in low obstruction though our studies are still in progress. We have also investigated the liver histologically and functionally (2) in obstructed dogs and although we have found definite and often marked impairment of liver function and histopathological changes we do not believe that they are sufficient to have accounted for death or to support the idea of a toxemia. Recently Dodd, Minot and Casparis found guanidine, a very toxic substance, present in the blood of infants suffering from intestinal intoxication, a disease which many believe is related to obstruction. Dr. Senn and I have followed this idea and have in fact found a high blood guanidine in a few patients and in some dogs with low intestinal obstruction. Our observations are too few to permit general conclusions, but we have some evidence that amines other than guanidine may be present.

Sudden release of distention. It is not surprising as a matter of fact that it is so difficult to demonstrate a toxin outside the lumen of an obstructed intestine. We know from many experimental and clinical observations that distention of the bowel causes an obstruction of venous as well as lymphatic return. This distention is sometimes very

great enough to cause gangrene especially of the wall opposite the mesentery where the circulation is the poorest. If this is true distention obviously diminishes absorption. The most recent experimental work has shown that absorption above an obstruction is in fact very slight (12). But consider what occurs when such a distention is suddenly relieved. Circulation through the collapsed bowel is immediately altered. Absorption may be accelerated for one thing by the improvement in blood flow. Then too a large area of paralyzed capillaries may be opened for engorgement from the general circulation, thus leaving the systemic circulation poorer in blood and fluids. Such a possibility has been suggested by certain experiments that Dr. Cole and I have just made on the cause of death following acute occlusion of the portal vein (4) which as is well known is a rapidly fatal procedure. We have found that there is an astonishing accumulation of blood trapped in the splanchnic area following portal ligation which is sufficient to account for the symptoms of shock and probably death from loss of blood and fluid alone. That is enough blood is lost from the systemic circulation into the intestinal capillaries to lower blood pressure below that compatible with life. What application if any this has to the problem of low obstruction cannot be said. We do know that the distention which occurs within the lumen of the intestines does actually produce a diminution or even a stoppage in portal outflow sufficient sometimes to produce a gangrene of the bowel. Whether there is a sufficient escape of blood and fluid into the obstructed intestine to lower blood pressure and cause death we do not know. Further investigations, we hope will give the answer. This is of course, all purely speculative but the practical point is that something occurs when the distended bowel suddenly collapses which I believe is deleterious to the patient and may cause sudden death.

SLOW DECOMPRESSION OF DISTENDED BOWEL

Regardless of the mechanism of sudden death I have attempted during the past year to avoid sudden release of distention by gradually decompressing the dilated bowel.

A mushroom catheter is placed into an obstructed loop and brought out through a separate stab wound so that the bowel lies in its natural position. The tube is clamped and released at frequent intervals so that drainage occurs progressively but slowly. Although the number of cases is still small the results were so striking I am tempted to report this procedure. It differs from the usual tube enterostomy which so often really fails to drain. It implies the minimum of operative trauma inasmuch as no attempt is made to cure the obstruction unless of course a strangulation is present in which case the mass is exteriorized for later resection. It emphasizes finally the conservation of the distention as a protective measure for several hours until it is gradually and harmlessly relieved. Dr Wangenstein of Minneapolis, on a recent visit told me he has been treating his cases by passing a duodenal tube and draining the obstructed contents from above, and in 12 cases has seen remarkable improvement in toxic symptoms during the course of several hours. I believe his results are due to the slow gradual decompression of the distended bowel. Further observations of course are needed before one can prove such an assumption. I wish to report one very striking instance from my own cases.

A young negro was admitted to the St. Louis City Hospital with a history of several days cramping pain and vomiting. A diagnosis of intestinal obstruction was made and operation advised but refused. He left the hospital but returned in 24 hours much more sick and with fecal vomiting dry skin fast pulse and more abdominal distention. Several liters of parenteral fluid were given and he was operated on under spinal anesthesia with intravenous acacia-saline to maintain blood pressure for his general condition was very poor. Both obstructed and collapsed bowel was seen after the abdomen was opened but little attempt was made to locate the obstruction aside from satisfying myself that there was no strangulation. The obstructed gut was tremendously distended bluish in color and on mere contact the serosa and muscularis stripped off. A loop lying in the upper left quadrant was carefully mobilized and a Pezzar (mushroom) catheter was introduced and brought out through a separate stab wound. Every 30 minutes 100 cubic centimeters of fluid was allowed to escape from the tube by releasing the clamp. During this time parenteral fluids were continuously given. I considered the prognosis poor for this was the type of case which does poorly and usually dies within a few hours or a day after operation. I was astonished

therefore to see a bright and cheerful patient the next morning with a flat abdomen normal pulse and temperature. Several liters drained from the tube during the first 24 hours. He passed gas the following day and went on to a complete recovery. Two weeks later just before we were planning on X-ray studies of his gastro-intestinal tract he developed cramps and vomiting and was operated on soon after. The obstruction was found to be a band crossing the mid ileum which was probably a remnant of the omphalo-mesenteric duct. It was cut. No further abnormalities were found. The wound was closed and the patient has been well since.

THE USE OF HYPERTONIC SALINE

I should like to mention briefly the use of hypertonic salt solution in intestinal obstruction originally advised in order to furnish an abundance of chloride ions to neutralize the supposed toxin. Its physiological effect is now known to be quite different. It is a powerful stimulant of intestinal peristalsis (14) and is an efficient way of promoting evacuation of a paralyzed distended bowel which after enterostomy will not drain sufficiently. Without an outlet for the obstructed contents its use of course, aggravates the distention quite as much as the use of purgatives.

THE USE OF HARTMANN'S SOLUTION

In the administration of parenteral fluids we have found of great value the modified Ringer's solution as made up by Dr Hartmann (9), of the Washington University School of Medicine. It is a physiological buffered solution containing in addition to calcium, potassium and sodium chloride sodium lactate. This lactate itself a calorogenic substance, on being oxidized yields bicarbonate which, slowly formed, directly combats any acidosis present and yet in the presence of alkalosis has no deleterious effect. The solution is made up in a concentrated form in ampuls and we add it either to distilled water or 5 per cent glucose and thus in one solution we have water, salts, buffer, and sugar. When mixed with the proper amount of distilled water it may be given subcutaneously or intravenously in the same manner as physiological saline solution. When made up in 5 per cent glucose the intravenous route is the best. Its effect is really remarkable in

high obstruction or indeed in any case where marked dehydration from vomiting, fistula or diarrhoea is the important condition. Patients may be kept alive and with normal pulse and temperature for weeks by giving several liters of combined solution per day. In uncomplicated low obstruction it is beneficial in so far as dehydration is present but of course is not specific or in general does not influence the progress of the disease without other means. The use of this combined solution while familiar to most pediatricians has been found by the surgical staff of Barnes Hospital to be a valuable addition to the surgical armamentarium because it seems to be more effective than ordinary saline and glucose. And here I might mention another point about the use of glucose alone. Glucose with out saline dilutes the blood temporarily stimulates renal excretion of salts, which finally leaves the blood much poorer than it was in both water and electrolytes. It therefore does decidedly more harm than good. Its use in conjunction with a solution containing salts, however, promotes diuresis and furnishes a source of needed calories.

CONSERVATIVE TREATMENT

All patients with intestinal obstruction receive several liters of combined solution at once. Gastric lavage is carried out. There is no objection in most cases to the use of a simple low enema to assist in ascertaining whether an obstruction is actually present. (The use of morphine occasionally relaxes a patient sufficiently to allow the obstruction to subside.) I believe one should not in general delay operation more than a few hours in the expectation of any spontaneous release of the obstruction. This of course does sometimes occur.

I remember the case of a young man whose ileum was perforated in several places by a bullet. The holes were all sutured. His postoperative course was smooth for 10 days when he developed acute obstruction for which it was found necessary to operate and a fibrous adhesion was found which was cut. He did well for 10 days and developed a second obstruction which was similarly treated and relieved. He balked, however, at operation when the third obstruction occurred for which he was being treated unsuccessfully by the usual conservative means. He left our care for another hospital. A few days later

our resident called the other doctor who told him that the jolting he got in the ambulance coming out must have been pretty severe, for on arrival he asked for a bed pan and had a voluminous evacuation. He has remained well since.

We cannot hope for such miracles more than rarely, however, and the danger of increasing distention and with it the possibility of strangulation and gangrene from delay is too great to justify much procrastination. Operation should therefore be done within a few hours unless obvious improvement is in progress.

COMPLETE EVACUATION OF THE OBSTRUCTED BOWEL

Since some surgeons have recommended complete emptying of the obstructed bowel to get rid of the toxic contents I should like to mention my experience with such an operation. The procedure is based on the idea that by removing the foul smelling poisonous fluid the toxemia is averted. I have discussed already the toxemia theory upon which this is based and the lack of proof that we are in fact dealing with a toxemia. It is, moreover, impossible to remove all the toxic contents. Enough remains to kill several patients if absorbed. It is the absorption that is important and after doing the evacuation operation in several patients, I felt sure that absorption if it occurs, was accelerated by the procedure. This is logical enough from the considerations already mentioned on the effect of the sudden release of distention. This is contrary to the report of Holden who records a mortality of under 6 per cent in 135 cases of acute obstruction basing his low figure on the fact that he eviscerates the patient and systematically strips the bowel from the ligament of Treitz, emptying all contents down to the point of obstruction. This conclusion in my opinion is unjustified until we know the duration of the obstruction in his cases. Early cases do well no matter what we do and his cases may have been for the most part early ones. In late cases too often a fatal outcome ensues no matter what is or is not done. It is moreover physically impossible to do much stripping in the really late cases for any handling leads to tearing of the serosa and muscularis.

THE TREATMENT OF STRANGULATION

If a strangulated, and especially gangrenous bowel is present the origin of symptoms is easy to explain and the exteniorization of the non viable gut is obviously indicated. To resect immediately and to make an anastomosis carries a high mortality unless the duration of the disease is short—say 12 to 18 hours. Otherwise we have the dilated bowel above to consider, that is to say the combination of strangulation and obstruction. To resect and anastomose of course, removes the involved bowel and relieves the obstruction at the same time, but though the operation may be easily and quickly performed these patients as already mentioned, too often die shortly after the operation from what I believe is a sudden release of distention. In the late cases there fore, where the mortality is high the non viable bowel is simply exteniorized for later resection and plastic repair and the obstructed bowel above decompressed gradually by fractional drainage of its contents.

SUMMARY

The cause of death in untreated complete high obstruction (stomach and duodenum) is probably a physicochemical one due to a depletion of water and salts from the blood into the vomitus or obstructed contents. The resulting dehydration can explain all of the so called "toxic" symptoms. Treatment with a modified Ringer's solution effectively restores the blood to normal, improves symptoms, and permits adequate surgical treatment without great risk.

The cause of death in low intestinal obstruction (ileum and colon) is probably differ

ent, but as yet there is little convincing evidence that a "toxemia" is present. Distention plays a prominent rôle and the idea is expressed that sudden release of distention may be an important factor in the fatal outcome. The operative treatment has therefore been confined in the late cases to gradual decompression of the distended intestine, strangulated bowel being merely exteniorized for later removal.

SURGICAL APPLICATIONS OF THE SCHILLING DIFFERENTIAL BLOOD COUNT¹

JOHN S. HARTER, M.D., AND CHAMP LYONS, M.D. BOSTON, MASSACHUSETTS

THE newer methods of classifying white blood cells in a differential count provide the surgeon with information of both diagnostic and prognostic import. The differential count in common usage was described by Ehrlich in 1891. This classification has proved its usefulness in detecting gross abnormalities of the blood picture but time after time has failed to show significant changes even in the presence of severe infection. The inadequacies of the Ehrlich differential count have led to the development of classifications that propose to group the cells according to their age. Successful results have been obtained particularly with the polymorphonuclear neutrophils. Arneth's classification (3) first presented in 1904 listed over 80 cell types and consequently proved too complex for practical application in clinical problems. Schilling (19) in 1911 modified Arneth's original conceptions sufficiently to adapt such a scheme to laboratory routine.

Schilling describes only two types of cells in addition to Ehrlich's familiar groups but by doing so finds the advantage of listing granulocytes (polymorphonuclear neutrophils) according to their relative maturity. The two additional cells are the "juvenile" (*jugendliche*) and the band form (*stabkernige* or *stab*). The familiar polymorphonuclear neutrophil with its multilobular nucleus is designated a segment. The classification of granulocytes in order of increasing maturity thereby becomes myelocytes, juveniles, bands, and segments.

Sufficiently accurate differential counts may be obtained by classifying 100 cells. With the blood smear prepared by the Wright stain² the cell types are recognized by Schilling as follows:

1. *Myelocyte* The largest cell of the granulocytic series is spherical in outline with blue

cytoplasm, usually containing fine granules. The nucleus is spherical and relatively large with fine chromatin network and several nucleoli.

2. *Juvenile* This is a large cell differing from the myelocyte in that its cytoplasm is a paler blue with slightly coarser granules. The nucleus is bean- or U-shaped usually containing one or two circumscribed nucleolar condensations. The nuclear chromatin is slightly more condensed than in the myelocyte. This cell is almost identical with Pappenheim's description of the metamyelocyte.

3. *Band* The cell is recognized by its rod or band-shaped nucleus containing condensed chromatin without nucleoli. The nucleus may take various forms more frequently resembling the letters U, Y, S or T. In addition, it is necessary to recognize the so called *degenerative band* with pyknotic, narrow, bizarre-shaped nucleus taking a darker or lighter stain than the typical band.

4. *Segment* The segment is a mature polymorphonuclear leucocyte characterized by a chromatin thread connecting adjacent lobes of the nucleus. The nuclear chromatin stains similarly to that seen in the band form.

In recording the differential count the following scheme is used. In the column at the extreme right under the heading *Neutrophils* appears the total number of cells that are subdivided into myelocytes, juveniles, bands, and segments.

THE SCHILLING HEMOGRAM

	WBC	Myelocytes	Juveniles	Bands	Segments	Myelocytes	Neutrophils
Standard Shift to left (granulocytes)	7,000	1					
Degenerative	25,000	12	26	4	9	0	90
	3,000		21	23	20	6	53

An increase of juveniles and band forms, usually with an associated decrease of lymphocytes and monocytes, is described as a *shift to*

¹The simplified method of staining the blood smear is undoubtedly the most accurate method of differentiating white blood cells. However, this highly specialized method requires so much time that it is hardly of clinical value to the surgeon.

the left Correspondingly, an increase of mature neutrophils usually with a restoration of lymphocytes and monocytes to normal or higher values is known as a *shift to the right*

A shift to the left with a graded increase of immature neutrophils is indicative of the active production or regeneration of white cells by the bone marrow hence this constitutes a *regenerative shift* This is the characteristic picture with an acute infection and the degree of shift to the left may be directly correlated with the extent or severity of the infection Diseases such as typhoid fever characterized by a leucopenia with neutropenia usually show a high percentage of degenerative band forms This type of reaction is the *degenerative shift*, the extreme examples of which are encountered in certain infections with a low white blood cell count and agranulocytosis or malignant neutropenia

Certain more or less physiological conditions are associated with a differential count that closely simulates a pathological blood picture. These must be kept in mind in interpreting a Schilling hemogram just as in the usual differential count We have found that the following conditions are most likely to cause confusion

1 A leucocytosis with shift to the left accompanying muscular exercise and intense emotion

2 Individual numerical variations according to age constitution and race

3 A moderate increase in the white cell count and shift to the left may be present in uncomplicated pregnancy

Most diseases and physiological conditions affecting the blood picture will fall in one of the following groups

Neutrophilia without shift (neutrophils 70 per cent or over)

- 1 With increased white blood cell count
 - a Physiological digestion (?), slight muscular activity and emotion
 - b Pathological superficial minor infections abortive cases of infectious diseases, hemorrhage, chlorosis polycythemia, tetanus, malignant tumors (uncomplicated) and after sodium chloride infusions

2 With normal or subnormal white blood cell counts

- a Physiological changes dependent upon the uneven distribution of cells in peripheral and internal organs
- b Pathological chlorosis (not constant), superficial minor infections hemorrhage sarcomatosis and malignant tumors (uncomplicated)

Neutrophilia with slight shift to left (Hyporegenerative, over 5 per cent bands)

- 1 The white blood cell count is usually increased but may be subnormal
 - a Physiological muscular activity, emotion and pregnancy
 - b Pathological mild infections superficial minor or encapsulated septic processes that are not extending, bacterial endocarditis, protozoan diseases, syphilis, hemorrhage, ulcerated tumors, lymphoblastoma, mildly active tuberculosis and tuberculous abscess formation

Neutrophilia with marked shift to left (Marked regeneration with juveniles)

- 1 Usually with increased white blood cell count
 - a. Physiological pregnancy, obstetrical labor and exercise.
 - b Pathological acute infectious diseases most of the acute protozoan diseases, acute and progressive septic processes, acute exacerbations of chronic infections and intoxications, as with carbon monoxide, heavy metal, and certain bacterial poisons.

Neutrophilia with extreme shift to left (Hyperregenerative, with myelocytes)

- 1 The white count may be increased, normal, or decreased
 - a. Physiological not found
 - b Pathological occurs in the most severe cases of sepsis and in disease or injury of bone marrow

Neutropenia (Absolute diminution of the neutrophils)

In these conditions the total number of

APPENDICITIS

	WBC	B	E	M	J	N	S	L	M	N
Standard	7,000						4	61	3	6
1. Chronic appendicitis	14,000			20	17	29	4		67	
2. Acute appendicitis	8,000			9	31	3	3		48	
3. Acute appendicitis	8,000			1	60	3			62	
4. Acute appendicitis with perforation	8,000			4	37	47	7	8	56	

In appendicitis the degree of shift to the left in the Schilling hemogram has been found to correlate with the severity of the infection as judged by clinical standards with greater consistency than either the total white blood cell count or the barlick differential count (6).

POSTOPERATIVE COURSE OF ACUTE APPENDICITIS WITHOUT COMPLICATIONS APPENDECTOMY WITHOUT DRAINAGE

	WBC	B	E	M	J	N	S	L	M	N
Standard	7,000						4	61	3	6
Pre-operative	8,000			8	60	1			8	
1st day postoperative	8,000			7	3	89				
2nd day postoperative	8,000			14	44	42				
3rd day postoperative	8,000			8	17	3	18			
4th day postoperative	8,000			3	8	89	3	67		
5th day postoperative	8,000			4	66	3	70			

There is decrease of the bands to slightly below normal and moderate lymphocytosis usually accompanied by slight monocytosis during the normal postoperative course of drained or removed focus of infection. The white blood cell count may increase or decrease slightly following operation. The degree of shift reflects the progress of the patient more accurately than does the total leucocyte count.

neutrophils is reduced. The leucopenia with bands and often a degenerative nuclear shift is due to reduced activity of the neutrophilic centers in the bone marrow. This picture occurs most frequently in the presence of typhoid fever, epidemic parotitis, Malta fever, grippe, chicken pox, acute poliomyelitis, sympathetic ophthalmia, and occasionally in tuberculosis.

In order to evaluate the practical usefulness of the Schilling differential count the hemogram was made a part of the routine blood examination on cases of sepsis admitted on the West Surgical Service of the Massachusetts General Hospital. These studies were performed in the routine laboratory by surgical internes without unusual training in hematology. A few cases typical of common types of sepsis are recorded below to illustrate the clinical application of this method of blood examination.

INTERPRETATION OF THE SCHILLING HEMOGRAM

The complete interpretation of the Schilling hemogram takes into consideration the distribution of the lymphocytes, monocytes, eosinophils, and basophils as well as the types of neutrophils. The monocytes and eosino-

POSTOPERATIVE COURSE OF ACUTE APPENDICITIS WITH PULMONARY COLLAPSE AND PERITONITIS APPENDECTOMY WITH DRAINAGE

	WBC	B	E	M	J	N	S	L	M	N
Standard	7,000						4	61	3	6
1st day postoperative	8,000			4	37	47	7	8	56	
2nd day postoperative	8,000			4	44	34	2	3	53	
3rd day postoperative	8,000			7	3	7	14	9	77	
4th day postoperative	8,000			7	43	8	17	3	71	
5th day postoperative	8,000			2	49	8	3	71		
6th day postoperative	16,000			4	53	9	16	7	70	
7th day postoperative	16,000			8	31	32	6	3	60	
8th day postoperative	8,000			20	49	13	4	78		

A pre-operative differential white blood cell count was not obtained in this case but the decreasing white blood cell count, its increasing shift to the left suggested complication. The pulmonary complication was reflected in the hemogram before the development of clinical signs. The increasing white blood cell count after the fifth day suggested improvement but the persistence of the shift to the left indicated residual infection. It was the shift as measured from the abdomen as the basis of the shift (6) which was the basis of the diagnosis. The increase in the white blood cell count with shift to the right the next day coincided with the subsiding infection.

APPENDECTOMY IN THE PRESENCE OF PREGNANCY

	WBC	B	E	M	J	N	S	L	M	N
Standard	7,000						4	61	3	6
Pre-operative	14,000			18	18	19	8	71		
1st day postoperative	8,000			8	30	10	34			
2nd day postoperative	8,000			3	52	3	47			

Pregnancy without complication may give blood picture resembling that of postoperative shift. The patient clinically presented signs in the right lower quadrant. There was no evidence of the leucocytosis. The hemogram did not help in the differential diagnosis. There was no evidence of acute infection at the time of operation.

neutrophils are decreased in number in advancing acute infections of surgical importance. In infection the number of lymphocytes has been found to reflect the resistance of the individual (12). Low lymphocyte counts occur particularly with advancing acute infections in patients with poor resistance. Normal or high lymphocyte count in the presence of a shift to the left is an indication of good resistance as seen in localized sepsis or chronic infection. The disappearance of neutrophils in recovery is associated with slight elevation of lymphocytes and monocytes. A transient basophilia has been noticed in postoperative leucocytosis.

The evaluation of the total white blood cell count on the basis of the types of neutrophils present is an index of the reaction of the individual to infection. An increasing shift to the left with a rising white blood cell count occurs when the individual shows an adequate response to the increased demand for white blood cells. An increasing shift to the left in the presence of a falling leucocyte count occurs with the inability of the individual to meet the

DIFFERENTIAL OF THE SCALP

	WBC	B	I	M	J	R	S	L	M	N
Standard	7,000	1	2	0	0	4	1	1	6	65
Pre-operative	17,100	0	0	3	10	54			0	0
1st day postoperative	7,500	0	0	0		54		11		35
2nd day postoperative	7,500	0	0	0		1	67	10		00

The presence of myelocytes with the low lymphocyte count denoted a severe infection with poor resistance on the part of the patient. However, a prompt shift to the right and an increase in lymphocytes followed drainage of the infection. A favorable prognosis was given the first day after operation (that was well borne out by the subsequent clinical course).

GANGRENE OF FOOT WITH INFECTION
AMPUTATION

	WBC	B	I	M	J	R	S	L	M	N
Standard	7,000	1			0	4	64	1	0	65
Pre-operative	6,200	0	0	8	83	3	1	3		75
2nd day postoperative	7,000	0		3	10	70	7	33	0	78

The presence of myelocytes and a large number of juvenile cells is associated with a severe infection. A good prognosis was given the second day after amputation because of the shift to the right. The Schilling differential count shows only a slight decrease in the myelocytes after operation, while the total number of neutrophils is the same before and after operation. The change in the total white blood cell count is also insignificant.

RHEUMATIC FEVER SIMULATING
OSTEOMYELITIS (NO OPERATION)

	WBC	B	I	M	J	D	S	L	M	N
Standard	7,000	1	0			4	64	1	0	65
On admission	11,100	0	0	0	7	33	3	0	0	0
4th day in hospital	10,500	1	3	0	0	57	33	4	30	

A boy of 12 years was admitted with a swollen, red, tender area over the distal end of the left tibia. There was a less pronounced process in the same region on the right side. Clinical observations suggested osteomyelitis. The haemogram showed only a slight lymphocytosis without shift to the left, a picture absolutely inconsistent with pyogenic infection particularly in a patient of this age.

demand for white cells. Insufficient response to the infection is seen in the cases of hyper-regenerative shift without leucocytosis. The decreased demand for white cells in subsiding infections results in an increase of the mature neutrophils and a shift to the right. This shift is frequently seen with a temporary elevation of the white blood cell count as the blood returns to normal.

The progress of a patient with an infection may be very accurately followed by frequent haemograms and white blood cell counts. However, adequate surgical treatment may quickly alter the blood picture and therefore the prognosis.

USE OF THE HÆMOGRAM IN OTHER CLINICS

Results similar to these have been obtained in surgical cases in other clinics. Baum has taken the haemogram as a true picture of organ pathology and has emphasized the value of repeated counts. He considers it a thoroughly reliable diagnostic and prognostic aid. Rezn

Fig. 1. Schematic representation of granulocytes as classified by the Schilling differential blood count. (After drawings by Miss Muriel McLatchie.)

Koff is in accord with this viewpoint and feels in addition that changes in the haemogram may antedate clinical symptoms. Yaguda in a study of 671 cases of appendicitis was able to correlate the degree of shift in the haemogram with the extent of the infectious process. This was also true in the 40 cases of appendicitis reported by Goodale and Manning. No shift was present in those cases in which normal appendices were found.

CONCLUSIONS

1 The Schilling differential count is readily adaptable in routine laboratory usage to replace the Ehrlich differential blood count.

2 It is of more value than the Ehrlich differential count in detecting the presence, degree and persistence of infection.

3 The Schilling haemogram is the simplest classification of neutrophils giving an adequate picture of the bone marrow response to infection.

CLINICAL SURGERY

FROM THE LAHEY CLINIC

THE SURGICAL MANAGEMENT OF VERY SMALL AND EARLY PULSION OESOPHAGEAL DIVERTICULA

FRANK H. LAHEY, M.D., F.A.C.S., BOSTON, MASSACHUSETTS

In our experience in performing the two stage excision of pulsion diverticula of the oesophagus in some 35 patients with no deaths we have been impressed with the fact that the fair but intermediate sized type is the easiest to manage surgically; the diverticulum with a sac large enough to be readily mobilized and implanted in the wound with the dome well above the level of the skin is the simplest type to operate upon (Figs. 1 and 2).

Very large oesophageal diverticula are often difficult to handle surgically, particularly since patients with them are often in bad risks because they have not received sufficient amounts of food on account of the long standing obstruction; in addition the aperture made by the opening of the diverticulum at its neck is often so large that dissection particularly on the right side may be somewhat troublesome (Fig. 2).

We have no real difficulty in treating large and intermediate sized diverticula by the two stage operation. On the other hand at the beginning of our experience we hesitated to operate upon patients with small sacs which were of insufficient diameter to permit the dome to reach above the level of the skin when implanted in the wound. With added experience however we have developed a plan whereby even the smallest diverticulum can be taken care of by the two stage procedure provided it is of sufficient size to have developed a sac with a distinct neck. We have operated upon several patients with extremely small oesophageal diverticula by the two stage plan quite safely and satisfactorily; the X ray of one which has just been successfully operated upon is shown in Figure 3.

In our opinion it is a real advantage to be able to operate while the diverticulum is still small. Because of the technical difficulty presented by such diverticula, there has been a distinct tendency to postpone operation until the sac has increased in size. This often results in the pa-

tient's undergoing for an unnecessary length of time the discomforts associated with a sac of considerable size such as regurgitation of food, partial obstruction and—as has happened in a few of the cases upon which we have operated—interference with sleep due to the accumulation of fluid contents in the sac during slumber, the contents running through the glottis into the trachea and producing attacks of choking. In 2 patients this has been one of the urgent symptoms which has prompted the seeking of relief and cases suffering from this complication should we believe be immediately submitted to surgical removal of the sac by the plan mentioned.

There has been some disagreement in the literature as to the wisdom of removing oesophageal diverticula by the one stage or two stage operative plan. As the result of our successful experience with the latter procedure as stated we do not feel like changing our method. We believe that in any large series of diverticula removed by the one stage plan there is almost certain to be an occasional one in which leakage will occur followed by mediastinitis and a fatality.

Dissection of oesophageal diverticula so that the entire neck of the sac is free and can be mobilized upward is at times difficult and requires meticulous technical precautions. Suture of the oesophagus on its posterior wall deep in the wound behind the trachea is of necessity difficult particularly since it must be done close to the pharynx where the oesophagus disappears beneath the lowest fibers of the inferior constrictor. The oesophagus ascends and descends constantly with swallowing. The oesophageal canal is always infected, and must therefore be in constant danger of leakage. We admit that with the accurate application of stitches sacs can doubtless be removed in one stage, the neck of the sac sutured and the occurrence of non fatal leakage usually prevented. Unfortunately however the situation is similar to that in all sutures of the alimentary canal.

Fig. 1. This roentgenogram shows the moderate sized sac, the ideal size for the two stage operation.

Fig. 2. This shows the very large sac in which two stage operation is very easy because the dome of the sac can be implanted well above the level of the skin but the dissection may be difficult due to the size of the aperture into the longitudinal oesophagus.

Fig. 3. This is the very small sized diverticulum concerning which this paper is written. This sac is about the size of a grape. It was in this type that up to the time of the development of this plan, operation was delayed until the sac had reached greater diameter.

through technical errors and inaccuracies—and they will occur in the very best of hands—through necrosis secondary to local loss of blood supply through inaccurate application of stitches, or through too tight ligatures, with pulling of stitches, leakage in any intestinal or oesophageal suture will occasionally happen in spite of the most painstaking attention to details. Leakage in oesophageal diverticula operations is into a fascial plane, which is admittedly a dangerous one this plane is represented in back by the prevertebral fascia, and in front by the pretracheal fascia, and leads directly into the mediastinum. Infection occurring along it can usually be controlled by drainage but occasionally a fatal mediastinitis will occur in spite of it.

We feel strongly therefore, that the two stage procedure, in which, provided the sac is not open there is no danger of dissemination of infection along the fascial plane, with consequent mediastinitis, is to be preferred, even though it may seem less surgical and that it will in a large series of cases result in a lower mortality. As we have repeatedly stated, if one out of one hundred patients operated upon by the one stage plan died as the result of leakage, but none of an equal

number operated upon by the two stage plan we should consider this a convincing argument in favor of the latter.

With this in mind, we have been greatly interested in developing a method whereby even the smallest sac can be safely operated on by the two stage plan, thus permitting early relief from distressing symptoms and in all probability producing local conditions in the oesophagus which will bring better postoperative results. The oesophageal diverticulum shown in Figure 3 for example is about the size of a small grape. It was nevertheless successfully removed by the two stage procedure.

The surgical approach to the small pulsion oesophageal diverticulum is exactly the same as that we have described for the large diverticulum. An incision is made either transversely above the clavicle or longitudinally in front of the sternomastoid. The belly of the omohyoid is cut, the middle thyroid veins are ligated and the lobe of the thyroid is turned forward. The inferior thyroid artery will seldom need to be ligated when the sac of the diverticulum is small. The sac is readily found under regional anaesthesia by asking the patient to swallow when it may readily be seen to ascend and descend in the wound (Fig 4).

The sac is picked up with tacking forceps and is carefully dissected from the overlying fibers of the cricopharyngeal muscle until it is entirely free at the top on the right side at the bottom and on the left side. When the diverticulum has been completely freed as it can be with adequate exposure and retraction so that the lower angle made between the diverticulum and the longitudinal wall of the oesophagus is entirely freed, the dome of the sac is gently lifted upward and approximated to the outer edge of the sternohyoid muscle at a point such that the dome of the sac is higher than the point at which the neck of the sac joins the longitudinal oesophagus. Two black silk stitches, as shown in Figure 5 are then passed through the submucosa of the sac and the outer edge of the sternohyoid muscles. Care is taken to make certain that these silk stitches penetrate only the submucosa and do not pass through the mucosa. If they pass through all the coats of the diverticulum they may easily cut out of the sac as the result of vomiting or swallowing with consequent leakage and infection within the fascial plane. With the dome of the sac fixed between the first and second stage operations to the sternohyoid muscles at a higher level than the neck of the sac there will be no accumulation of material within the sac, the patient will

be able to swallow immediately with no regurgitation, and the distressing regurgitation of food into the larynx during sleep spoken of previously will no longer occur.

With the sac sutured to the prethyroid muscles a cigarette drain is placed in the lower angle of the wound, so that granulations and adhesions will occur behind the oesophagus in the fascial plane made by the prevertebral fascia in back and the pretracheal fascia in front thus guarding the patient against mediastinitis at the second stage operation. The wound is then closed by interrupted sutures and the sac is thus left completely buried in the wound fixed as it is to the sternohyoid muscle.

Following this stage patients swallow without difficulty can be out of bed the day after operation since it is done under novocain cervical block are immediately relieved of all symptoms of obstruction and regurgitation and may possibly go on indefinitely without difficulty in swallowing even if the second stage removal of the sac is not done. The second stage removal is however safe and simple there is always the possibility that the sac may dilate and for that reason the removal should be done.

At the end of 10 days the wound is reopened. The sac is readily discovered by following the edge of the sternohyoid muscle up to the point where the two black silk stitches which attach the sac to it are located. These stitches are cut and the sac drops away from the muscle and is immediately available for removal.

We have had no difficulty in the sac's pulling away from the sternohyoid muscle between stages no matter how small it was. The oesophagus is lax it readily dislocates to one side and any tension on the sac of the diverticulum no matter how small is we think, readily compensated for by rotation of the oesophagus and by lateral dislocation of that structure to the side on which the diverticulum sac is sutured.

With the sac of the diverticulum freed at the second stage two tacking forceps as shown in Figure 6 are placed upon the dome of the sac traction is made upon it and the neck of the sac is freed of adhesions and demonstrated. An incision with a knife is then made about the neck of the sac as shown in Figure 6 through the submucosa and what remains of muscularis down to but not through the mucosa. This incision is carried around the entire neck of the sac, a ligature of fine chromic catgut is then tied about the neck of mucosa the sac is cut away the stump of mucosa is canterized a cigarette drain is carried down to the stump of mucosa as in an appen-

Fig. 4. The main illustration shows the small sized sac dissected free and resting in the wound. Insert a shows diagrammatically the size of the small sac.

Fig. 5. This illustration shows the dome of the sac dissected free and sutured with two black silk stitches to the edge of the sternohyoid muscle to fix it at this point. The wound is then closed so that the sac is buried in the wound. At the end of 10 to 12 days, the wound is reopened. The sac can then readily be discovered by following the edge of the prethyroid muscles and demonstrating the two silk stitches which attach the sac to it.

Fig. 6. In insert a the sac has been detached from the sternohyoid muscle. The subocoma has been incised and a ligature passed around the mucosa lining the diverticulum. In insert b this has been tied. In insert c it has been cut away as in appendectomy. In insert d a drain has been carried up to the point of ligature and emerges from the lower angle of the wound. The wound has been closed in layers about the drain.

divertomy and the wound is closed about the drain. This procedure has resulted in little or no leakage, and patients have usually been able to leave the hospital within 8 to 10 days following the second stage removal.

We have been interested in developing this plan of operating upon small pulsion cesophageal diverticula because of our conviction that any patient with this condition will show constantly increasing size of the diverticulum the longer he continues with it. With increase in size will come increase in symptoms, likewise lengthening years, with the patient less able to withstand surgical operation. The average age of the 35 patients operated upon for pulsion cesophageal diverticula was 58½. The youngest was 43 and the oldest 80.

As stated in all our earlier discussions patients who have been operated upon for pulsion cesophageal diverticulum should be bougied after operation at intervals of 2 to 3 months for at least a year regardless of whether procedure has been by the one stage or two stage plan. One of the logical theories of the origin of cesophageal diverticulum attributes it to spasm and obstruction of the cricopharyngeal muscle fibers at the pharyngo-cesophageal junction. Furthermore, whether the neck of the diverticulum be closed by a one stage or two stage procedure, there will

be some scarring on the posterior wall of the cesophagus. It is therefore desirable and not particularly disturbing to patients to pass olive tipped bougies by the point of closure at the pharyngo-cesophageal junction for the period indicated in order to dilate the cesophagus itself at this point and overcome any persisting spasm of the cricopharyngeal muscle fibers.

No patient should be dilated by bougie after cesophageal diverticulum operations unless he has previously swallowed a string so that the bougie may be accurately guided by the point of suture. Patients are given a spool of No. 7 or No. 9 silk and instructed to swallow at least 10 feet starting the day before they are to come for bougieing. Olive tipped bougies on a whale bone carrier are then threaded upon the swallowed string the string is wrapped around the finger of the person passing the bougie and stretched when the bougie readily passes the point in the cesophagus from which the diverticulum was removed and into the longitudinal cesophagus. Unless this method of bougieing upon a string guide is employed it is possible to engage the bougie

against a shelf of cesophageal mucosa and do damage by forcible pressure.

CONCLUSIONS

1. It is undesirable that patients be compelled to put up with the symptoms of pulsion cesophageal diverticulum until it has reached such a size that it can be implanted well above the level of the skin.

2. Pulsion cesophageal diverticula do not disappear but tend to increase in size and to produce more and more marked symptoms.

3. It is desirable to remove pulsion cesophageal diverticula no matter how small they are provided that they have produced a sac with a distinct neck.

4. The sac may be implanted in the wound and safely removed by the two stage procedure without the danger of leakage and mediastinitis.

5. It is desirable regardless of whether removal is by the one stage or two stage procedure, that patients be bougieed after operation every 2 to 3 months for a year and that the bougie be passed upon a string guide.

FROM THE UNIVERSITY OF ROCHESTER SCHOOL OF MEDICINE

THE OPERATION FOR PERFORATIONS OF THE
CERVICAL OESOPHAGUS

HERMAN E. PEARSE, JR., M.D. ROCHESTER, NEW YORK

From The Department of Surgery The University of Rochester School of Medicine and Dentistry Rochester New York

PERFORATION of the oesophagus endangers life from infection of the mediastinum. This holds true irrespective of the location of the perforation, whether cervical or thoracic. Extravasation from the thoracic portion allows direct contamination of the mediastinal structures with such a virulent infection resulting that few patients have the resistance to survive. Efforts at surgical relief have been disappointing.

On the other hand the mediastinitis following cervical perforation is an indirect effect. It results from a dependent spread of infection from the neck into the chest along the fascial spaces. There is abundant evidence to prove that a direct communication exists between the cervical region and the mediastinum (1). This is due to the fact that during embryological development the mediastinal structures originate in the neck and migrate into the chest carrying their enveloping fascia with them. The conception that the mediastinum begins at the diaphragm and ends at the base of the skull (2) is logical since at no place is there a transverse demarcation to segregate these regions. The blocking of the paths of communication between chest and neck effectively separates the parts. If this is done before the infection has gravitated to the mediastinum then mediastinitis is prevented.

In the controversy that has arisen among endoscopists as to whether infection should be drained through the endoscope or by an external incision it would appear that this fact has been lost sight of. There is no doubt that a localized abscess beside the cervical oesophagus can be drained by the oesophagoscope. But who feels competent to predict that the infection will localize and not spread into the mediastinum? Should the oesophagus be exempt from the rules, which experience has dictated for early surgical intervention in case of perforation of other organs, as from peptic ulcer an inflamed appendix, or a traumatized urethra? It should be kept in mind that the patient does not die of the perforated cervical oesophagus, *per se* nor does he necessarily die from the infection in the neck but usually dies from mediastinitis, the indirect result of the perforation. It is possible for the surgeon to

do what nature has left undone, namely to create a transverse barrier between the neck and the chest. Thus the external operation for perforation of the cervical oesophagus will have a two-fold purpose, first to block the fascial spaces to the mediastinum and second to evacuate extravasated material.

The operation designed for this purpose was originally described by Marchlik. This procedure which has not been modified to date consists of two parts. After a long incision is made parallel to the anterior border of the sternocleidomastoid muscle the space low in the neck between the carotid sheath and the trachea, oesophagus, and thyroid gland is packed with gauze. This space is called the anterior cervical mediastinum. The dissection is carried upward, the omohyoid muscle is cut and the so-called posterior cervical mediastinum is reached. This space is between the vascular sheath laterally the prevertebral fascia posteriorly and the oesophagus, trachea, and superior pole of the thyroid gland medially. This space is packed and any extravasated material present is drained.

Palmer describes the Marchlik operation as he learned it in Hajek's clinic in Vienna as follows. An incision is made from the mastoid to the sternum. The sternocleidomastoid muscle is retracted "until the vascular sheath is reached." This is called the anterior cervical mediastinum and is tamponed with iodoform gauze. The dissection is carried upward the omohyoid is cut and by gently lifting the thyroid forward with blunt retractor the posterior cervical mediastinum is reached. The index finger may now be inserted until the cervical vertebrae are encountered. This area is tamponed and the original source of the infection is sought if the operator desires. The same description is given by Keiper (3). No mention of the operation was given in the modern textbooks or systems of surgery or otorhinolaryngology that were consulted.

The operation as originally performed in this clinic differed in a few details but not in essential principles. A smaller incision was used either transverse or parallel to the anterior border of the sternocleidomastoid muscle just above its clavicu-

Fig 1. A diagrammatic front and cross section, b view from a case in which the standard operation was done but where infection gravitated to the mediastinum behind the esophagus. This and a similar case demonstrated the necessity of blocking the post-esophageal space

lar attachment. The omohyoid muscle was not cut. The space between the carotid sheath laterally and the trachea, thyroid and esophagus was packed down to the vertebral column in the accepted manner. The carotid sheath was occasionally opened and drained.

After several years' experience with this operation it became evident that it had two defects. The first of these is that the packing above the level of the omohyoid in the posterior cervical mediastinum of Marschik was too high. The primary purpose of this packing is to create a barrier against the spread of infection into the mediastinum. By placing it so high in the neck it is conceivably possible to block the space above the point of perforation and hence do nothing to prevent dependent drainage. But exposure of this space at a lower level is difficult because of the interposition of the thyroid gland. The obvious solution for anyone familiar with the technique of thyroid surgery is to mobilize the gland by freeing its lateral vascular attachments and turn it medially out of the way. This mobilization of the thyroid gland allows the lowest possible packing and disposes of the first objection.

The second fault in the original Marschik procedure was discovered by postmortem dissection in two cases. In one of these the operation was done but despite this the patient developed mediastinitis and died. At autopsy it was found that

the infection had tracked down *behind* the esophagus (Fig 1). A second patient who had a posterior perforation died without operation from mediastinitis. Dissection revealed no infection of the spaces which would have been packed at operation but instead a small tract of infection going down immediately behind the esophagus. From the experience with these 2 cases it was decided that the Marschik operation was incomplete in so far as the space behind the esophagus was not blocked. Furstenberg has pointed out the direct communication of this space with the mediastinum.

TECHNIQUE

The operation as it is now performed, is as follows. A 3 inch incision is made parallel to the clavicular attachment of the anterior border of the sternocleidomastoid muscle. This muscle is identified and retracted laterally after incision of the superficial cervical fascia. The dissection is carried down to the carotid sheath; the fascia and muscle fibers of the sternohyoid and sternothyroid muscles are separated, and the lateral surface of the thyroid gland is exposed. It is usually found that the gland is held down by the middle thyroid vein (Fig 2). After ligation and division of this attachment the thyroid gland is rotated medially (Fig 3). This may be all that is needed to expose the esophagus. In some instances the inferior thyroid artery may limit the retraction of

Fig. 3. The exposure of the lower cervical esophagus is usually prevented by the lateral vascular attachments of the thyroid gland.

Fig. 4. A drawing made from a case of laceration of the esophagus from clam shell which shows the exposure obtained. For clarity the drawing is made with a larger incision than that actually used (insert). The operative incision was lower and its upper angle was level with the top of the laceration. The dotted line shows the limits of dependent spread of infection. The patient recovered.

Fig. 5. The division of the middle thyroid vein and if necessary of the inferior thyroid artery permits the medial retraction of the thyroid gland. The dissection should be kept as low as the manubrium and clavicle permit.

the thyroid gland. If this occurs, the artery is doubly ligated and divided at its point of emergence from beneath the carotid. The thyroid gland may then be rotated medially and a free exposure of the esophagus obtained illustrated by Figure 4 which is made from a case operated on 40 hours after perforation of the cervical esophagus, with recovery.

Fig. 6. A cross section which illustrates how the finger is inserted behind the esophagus to allow packing of the post-esophageal space. A bilateral incision is shown but if the process is limited to one side of the neck a single incision is used.

Fig. 6. b. A side view of a dissection on a cadaver to show the potential space existing behind the oesophagus. The obliteration of this space by packing (arrow) prevents dependent drainage. c and d are diagrammatic cross sections to show the position of the packing with unilateral and bilateral incisions, respectively.

After the structures have been exposed in this manner the finger is gently inserted behind the oesophagus to separate it from the prevertebral fascia (Fig. 5). This is surprisingly easy since there is only filmy areolar tissue in the post-oesophageal space. The tip of the finger is carried beyond the oesophagus to the opposite side. Gauze or a drain is then inserted with the tip extending beyond the oesophagus and brought out behind this structure then lateral to it and to the trachea and thyroid gland and medial to the carotid sheath and sternocleidomastoid muscle. If the symptoms are referable to only one side of the neck, then the operation may be terminated. If bilateral involvement is apparent, then a similar incision to that already described is made on the opposite side and a drain is inserted down to meet that already placed. This serves to pack the

fascial spaces beside and behind the oesophagus and effectively blocks all paths of spread to the mediastinum (Fig. 6).

This operation is done under local anaesthesia by regional block of the cervical nerves at the posterior border of the sternocleidomastoid muscle. A small amount of intracutaneous infiltration may be used in the line of the skin incision. The procedure does not cause shock and should involve less risk than the average operation for goiter. The choice of the skin incisions used is optional. For a bilateral dissection the transverse incision might be used. The only objection to it is the necessity for undercutting the flaps to gain exposure which opens a raw area to possible infection. The type of material used for packing depends upon the conditions found. If no infected or extravasated material is encountered then

iodoform gauze is used. If however it is desired to evacuate infected material a rubber drain is inserted since it is less apt to act as an obturator than is gauze.

The life saving object for the operation is to block the paths of spread of infection to the mediastinum. This should be done first. During this procedure extravasated material may be encountered and drained. If it is not it is debatable whether or not the point of perforation should be searched for and a drain placed down to it. It is felt that this should be decided by the circumstances of each individual case. Search for and drainage to the perforation is probably unnecessary since the infection will tend to gravitate down to the region of dissection and from there will have a vent to the outside.

The only problem in the postoperative care is to furnish adequate food and fluids while keeping the esophagus at rest. This may be done by inserting a small catheter into the stomach for feeding. Nourishment by hyperdermoclysis vein or rectum may be given. If the perforation is large gastrostomy is probably the preferable method.

Due to the development of esophagoscopy patients with perforation of the esophagus are seen by the endoscopist. It is his duty to decide whether perforation exists and when external operation is needed. The burden of management is his. But we have found that close co-operation between the endoscopist and surgeon leads to a mutual understanding and appreciation of the problems involved with a consequent benefit to the patient.

Our rules for management of the various types of perforation of the cervical esophagus have

recently been presented (2). They will not be repeated here except to reiterate the contention that since many if not a majority of perforations occur in the cervical esophagus and since death usually occurs from the dependent spread of infection to the mediastinum and since this spread may be prevented by an operation without undue risk, then all outspoken cases of perforation of the cervical esophagus deserve early external operation. This, in order that the surgeon may do what nature has failed to do namely to separate the fascial spaces of the neck from those of the chest.

SUMMARY

Perforations of the cervical esophagus frequently result in a fatal spread of infection to the mediastinum. This may usually be prevented by early operation. The original procedure of Marschlik for this purpose has been modified by a low cervical exposure obtained from mobilization of the thyroid gland and by blocking the fascial space behind the esophagus.

BENNETT'S FRACTURE AND OTHER FRACTURES OF THE FIRST METACARPAL

R. W. MCNEARY, M.D., F.A.C.S., AND MANUELLI LICHTENSTEIN, M.D., CHICAGO

EDWARD HALLORAN BENNETT was professor of surgery at Trinity College, Dublin. He was born in Cork, April 9, 1817. His medical education was obtained at Trinity College from which he received the degree of M.B. in 1859. He was immediately appointed demonstrator of anatomy from which position he rose rapidly and in 1864 succeeded J. K. Barton as University anatomist. While in this capacity he made use of the wealth of material at his disposal and was able to collect sufficient specimens of bone injuries to speak with authority in this field of bone pathology. In 1863 he became a fellow in the Royal College of Surgeons, was soon made councillor and in 1884 became president. He was one of the promoters of the union of medical societies in Dublin which resulted in the formation of the Royal Academy of Medicine of which in 1897, he became president. His labors in general surgery were obscured by his special interest in bone disease.

To his fellow practitioners he was always a model of honor and uprightness. No one ever heard it said that Bennett did a crooked thing. He was blunt, sometimes emphatically so, but he always said what he believed to be the truth although that might not be pleasant to hear. He was a man of strong personality and in his criticisms of other men's work he was very outspoken but never unfair. He never said an unkind word of anyone. He was thoroughly straightforward in all his ways and he detested anything underhanded. The result was as might be expected that no man had fewer enemies or more friends.

His manner toward the poor patients in the hospital was gentle to a degree while his fondness for children was proverbial so that he was a great fa-

vorite with them. He was a man of retiring habits and his figure was rarely seen on public platforms or at great social gatherings.

He loved teaching the students in the hospital wards were they the most junior or the most advanced and nothing did he enjoy more than discussing with them some difficult case or propounding some points of diagnostic interest. His liveliest interest lay in the diagnosis and the pathology of rare fractures. He had a facility for awakening the interest of students and of attaching them to him as loyal and believing followers. If he sometimes appeared brusque in manner or in tone his students knew he was at heart generous, encouraging, a just and tolerant judge, a man devoted to their interests and always helpful in those things that led to their success.

He was the colleague of men who seem to have directly inherited and brought to their profession in a later day the manners of eighteenth century Dublin—a culture that went hand in hand with a kind and robust humanity. He maintained while availing himself of modern scientific resources, the attitude toward life of a generation who were

never forgetful of the high import and dignity of their profession and who never allowed science to defeat its object or leave them too well equipped but too little capable. He was dignified without pedantry and cultured without arrogance.

When he lectured as university professor, he came to treat of surgery, having at his command the resources of literature and a great and nice knowledge of the Classics. His lectures were learned and academical far removed from mere recitals of facts that under the name of science become impersonal and inorganic because they lack the teacher who can assimilate and subordinate them

Edward Halloran Bennett—1837-1907

to their proper ends of humanity. One could see with what reverence he esteemed his calling if only from the respect and enthusiasm with which he always spoke of the work of his colleagues or his predecessors. He would dwell on names well known in medicine with admiration and revivify them with his own personality until the pupils on the benches shared his enthusiasm.

Before the advent of X-ray examinations, the diagnosis of bone injuries was based on a careful consideration of the nature and manner of the trauma, the symptoms noted by the patient and the physical findings derived after patient and diligent examination. The establishment of a pathological entity or type of fracture was accomplished by the accumulation of specimens in the pathological museums of the medical schools and large hospitals. A correlation of the clinical findings with the illustrative pathological specimens served as a basis for the establishment of a clinical entity.

As an example of the foregoing the fracture described by Bennett and since then known as Bennett's fracture may be cited. While the use of proper names has been grudgingly condoned in recent medical literature, no greater tribute to the painstaking efforts of the surgeons of the pre-roentgen era can be conferred than the retention of the name of this observer as an object lesson to present day students whose work has been greatly simplified by the use of roentgen ray examinations. A perusal of the writings which called the attention of the profession to this lesion is worthy of our consideration.

In 1881 Bennett exhibited before the Dublin Pathological Society a series of united fractures of metacarpal bones, 9 in number all from the right hand of which 5 were fractures of the first metacarpal bone. Concerning these 5, he stated:

I each of the five examples of fracture of the thumb allowing for shades of difference, such as must always exist, the type and character of the fracture is always the same—forms and type of fracture not hitherto described in these bones. The fracture passes obliquely (s.e.k. in the cut) (FIG. 1)

Fig. Original cut illustrating Bennett's fracture

He had a wider experience than the generality of men and a wider humanity. He knew life well and the more he learned of it the more he admired it. His insight did not sour him for his was a great sanity. He was kind and forbearing—intolerant only of pretense.

He died in Dublin June 21, 1907 in his seventy-first year.

through the base of the bone, detaching the greater part of the articular facet with that piece of the bone supporting it, which projects into the palm. In all these specimens, the dorsal surface of the bone is free from any implication in the fracture, and this fact, combined with the small amount of displacement which occurs, rendered the fracture one extremely liable to escape detection.

So trivial an injury does this appear to be and the specimens show so little deformity except in some the signs of arthritis consequent on it, I might fairly be asked what importance attaches to the correct diagnosis. All will admit that a correct diagnosis even in trivial injuries is desirable but in this case the diagnosis is essential to a correct prognosis and here lies the importance of the injury. Seeing the value of the movements of the thumb no injury of it is to be lightly regarded and this fracture though it united readily by bone and with almost unperceptible deformity renders the thumb for many months lame and aches.

At the annual meeting of the British Medical Association held in Cardiff July 1885 in an address delivered at the opening of the section of Surgery, Bennett stated after showing the importance of assembling specimens of fractures:

The small size of the bones and the light value, clinically which my surgeons have been apt to assign to simple fractures of the metacarpus, delayed my study of them, and so, perhaps, the result has been all the better for, without some time spent in accumulating, a number sufficient to attract attention could not have been reached. Taking at last the group into closer study I was struck by the fact that one particular fracture outnumbered all others. Now if we look to the series before us, remarkable fact is disclosed. Amongst these fractures, there occur six examples of fracture of the base of the metacarpal of the right thumb, and no others of this bone. In each of these the injury is the same. Most remarkable is the fact that in every case the accident has been on the right side of the body. Certainly this injury once we know of its existence becomes vastly more common than any other of the metacarpus. If left to itself it unites with such deformity as this case shows, trivial deformity after all. Why then deem the matter worthy of the notice of this surgical section of the British Medical Association. Simply for this reason, that I had ample proof that a hand so injured remains under the best of treatment long disabled and without treatment for a greatly longer time. When we consider the value of the right thumb to anyone who lives by handicraft or indeed to any rich or poor we should not let unnoticed and undiagnosed this common injury.

In the *British Medical Journal* of July 3, 1886 Bennett published a résumé of his previous articles reported in 1882 and 1885. He stated:

I now write this short note to make a correction in my account of the injury which, though of secondary impor-

Fig. 2. Types of fracture of first metacarpal bone.

tance only. I prefer to make myself rather than have it made by another. I stated that every example I had seen in the living or dead occurred in the right thumb. I avoided committing myself to the assertion that it could not occur on the left side. I merely said "most remarkable is the fact that in every case the accident had been on the right side of the body." I am now able to supply a drawing taken from a left hand deformed by the fracture and to record the observation of two other examples on the left side in patients seen this season in Sir P. Dunn's hospital. Thus I hope to correct whatever of error might have arisen from my record of my experience in August last.

The views expressed by Bennett concerning the importance of the thumb have not changed since his era. This is well exemplified by the fact that the State of Illinois Industrial Commission regards the value of the thumb as 60 weeks out of a total value for the entire hand of 185 weeks. Thus practically one-third of the value of the hand is vested in the thumb on the basis of utility in manual work.

Not all fractures of the first metacarpal correspond to Bennett's description. There has been considerable confusion of terms in descriptions of fractures of the first metacarpal and the classi-

fications listed below summarize the various types of fractures of this bone (Fig. 2).

I. At the base.

a. Intra-articular.

1. Bennett type
2. Rolando type

b. Extra-articular.

1. Transverse
2. Oblique
3. Complicated

II. The shaft.

1. Transverse
2. Oblique
3. Longitudinal

III. The head.

1. Transverse

Winterstein cites some interesting statistics on the relative distribution of fracture sites in 200 cases of fracture of the first metacarpal.

29 per cent Bennett type	} Base 80 per cent of all
7 per cent Rolando type	
10 per cent extra-articular—oblique	
25 per cent extra-articular—transverse	
9 per cent complicated—several varieties	

Fig. 3. Internal architecture of first metacarpal bone (after Magliulo)

1 1/2 per cent oblique	} Shaft
per cent transverse	
per cent longitudinal	
2 1/2 per cent transverse	} Head
5 per cent evulsion of capsule	
3-4 per cent epiphyseal fracture—Bennett	
2 per cent sesamoid bone fracture with head	

These fractures were divided

60 per cent in right hand, 9-5 per cent in men. It was found that direct trauma was usually of occupational origin while indirect trauma was due to falls, manipulations of thumb etc.

ANATOMICAL DESCRIPTION

The first metacarpal bone presents a body, a distal extremity or head and a proximal extremity or base. The body has a radial and an ulnar border. The palmar surface gives attachment to the muscles of the thenar eminence while the dorsal surface is flat with a rounded extremity toward the base. The proximal articular surface is saddle shaped with a dorsopalmar concavity and a slight lateral convexity. The dorsopalmar concavity presents a dorsal portion which lies in a straight line with the body of the metacarpal and a palmar portion which projects outward from the body of the metacarpal at an angle.

Corresponding with this gross anatomical description is an internal architecture made up of layers of lamellae which assume a definite shape and to a great extent determine the deformities produced when fracture occurs. Recent studies of Magliulo have clearly brought out the internal structure of the bone in the various age groups.

In adolescents (Fig. 3a) the diaphyseal cylinder is rather thin and little developed at the base. Two systems of lamellae are seen—a posterior and an anterior of almost equal dimensions. Although these lamellae are interrupted by the incomplete

ossification they retain the volodorsal direction in the posterior part. The lamellae are very thin at the head of the metacarpus but an arched bundle passes from the volar part of the neck to the back.

In adults from 20 to 27 years (Fig. 3b) at the base the anterior system of lamellae becomes triangular in form and is more robust than the posterior group which is much smaller and made up of a few very thin lamellae. The head preserves also the arrangement of the two systems of trabeculae that is the anterior and posterior systems.

In adults over 27 years (Fig. 3c) the compact tissue of the diaphyseal cylinder is generally thicker and the thickness is greater on the volar or concave than on the dorsal face where with advancing age, the compact tissue becomes thinner and finally changes to a thin dorsal layer (Fig. 3d). At the base the anterior and posterior systems of lamellae are preserved except that the posterior system is small and the start of rarefaction of the spongy tissue of the epiphysis is present. The compact tissue of the dorsal surface thins to only one lamina while in the volar surface it has a greater thickness. At the base, the anterior triangular system is present while the posterior system is lacking having been replaced by areolar tissue. At the head only the anterior system is well developed.

From the foregoing it may be seen that the bony tissue of the diaphysis of the first metacarpus in the various ages is more developed in the anterior surface than in the posterior surface. At the base in all ages there is a system of trabeculae in dorso-volar direction with lamellae which are parallel to one another which form in their entirety a bundle, triangular in shape, the base of which occupies four fifths of the articular surface and the apex of which lies on the concave surface of the metacarpus at the point of union of the diaphysis with the superior epiphysis.

MECHANISM OF FRACTURE

In describing the mechanism of fractures into the proximal joint, Rolando states that the dorsal articular process presents a much greater resistance to external violence than the palmar articular process, especially in injuries which act in the direction of the longitudinal axis of the metacarpal. The effect of this violence is to render the angle formed by the palmar articular process with the palmar surface of the metacarpal more acute. This results in an oblique fracture at the base of the process. The fracture then radiates from a point near the center of the articular surface to the

palmar surface. This is the mechanism by which Bennett's fracture is produced. The anterior triangular system of trabeculae previously described are practically sheared off from the shaft of the bone. In this fracture the dorsal articular process and the body of the bone tend to become dislocated dorsally but this dislocation can only be incomplete if the ligaments uniting the trapezium with the metacarpus are intact. In those cases in which violence is very severe or long continued and is in the longitudinal axis of the metacarpus it may lead to a fracture of the more resistant or dorsal articular process. In these cases there is a Y fracture in which the upper extremity of the first metacarpus is divided into three fragments two of which correspond to the base and are dorsal and palmar while the other corresponds to the shaft of the bone. This type is known as the fracture of Rolando. The articular fragment on the palmar surface constantly turns toward the thenar eminence. The dorsal articular fragment retains its relations with the trapezium. The lower fragment of the diaphysis may present a dorsal luxation as in Bennett's fracture or there may be no dislocation.

The two types of intra articular fracture that of Bennett and that of Rolando correspond to fractures along the internal lamellae of the base.

The mechanism of production of fractures of the first metacarpus has been investigated experimentally on the cadaver. Magliulo found that in 9 experiments where the thumb was abducted and slightly extended a blow on the dorsum resulted in fractures of the Bennett type in 4, fracture of the trapezium in 1, laceration of the ligaments in 1 and no result in 3.

He concluded from his work that the mechanism of fracture depended upon (1) the architecture of bone (2) the age of patient (3) the degree of extension and flexion (4) the action of trauma.

The treatment of fractures of the first metacarpal is of importance because of the associated pathology which develops. Faulty union atrophy of muscles of the thenar eminence weakness of the grip all contribute to the disability which may follow a simple fracture. In all of the extra articular types fixation in a position of extreme abduction will retain the web of the first metacarpal space and permit abduction when the splint is removed.

In the Rolando type of fracture simple abduction is usually sufficient to produce approximation of the fragments of bone. The prognosis in this type of fracture is better than in the Bennett type because of the usual absence of upward dislocation of the shaft found in the latter.

In the Bennett type the prognosis being not so favorable special effort must be directed to overcome the pathological displacement. In addition to the extreme abduction suggested for the other type of fracture longitudinal traction is essential if upward dislocation of the shaft has occurred. Many interesting procedures have been devised with this object in view.

Lambotte in 1908 produced osteosynthesis by nailing together the fragments. Imbert and Cotatorda in 1923 reported their procedure of osteosynthesis which did not differ radically from Lambotte's method. Baun used a nail driven through the distal fragment for the purpose of longitudinal traction.

Recently the incorporation of a wire loop in a plaster cast about the wrist has been utilized as a means of support for longitudinal traction produced by means of adhesive strips and rubber bands.

SUMMARY

Fractures of the base of the first metacarpal bone are most numerous occurring in approximately 80 per cent of all fractures of the first metacarpal bone. Only one fourth of these conform to the description of the Bennett type of fracture. This type of fracture is important because of the functional disability which follows when the fractured bone is allowed to heal without replacement of the fragments in correct apposition.

ADENOMA OF THE AMPULLA OF VATER

FREDERICK CHRISTOPHER B.S., M.D. F.A.C.S., EVANSTON ILLINOIS

Associate Professor of Surgery Northwestern University Medical School; Attending Surgeon, Evanston (Chicago) Hospital

BENIGN tumors involving the extrahepatic bile passages are extremely uncommon. A careful search of the literature discloses but 41 cases the author adds 1 case. The authenticity of some of the earlier cases is somewhat open to question. Including the author's case, the relative frequency of the different types of tumors is papilloma and polyp 16 adenoma 15 lipoma, 4 fibroma, 2 neuroma, 2 granuloma, 2 melanoma (classified as benign) 1, carcinoid 1. Practically all the patients afflicted were of middle age or older. Most of them had an associated jaundice and other obstructive symptoms. In 6 cases the tumor seemed definitely to involve the ampulla of Vater. In some cases the tumors were successfully removed at operation and in a few the tumors were found by chance at autopsy. It is noticeable that the lesion has been given increasing recognition in the last 50 years.

In their discussion of this subject, Savy, Bonnet, and Martin¹ state that "epithelial tumors constitute the great majority of benign neoplasms of the biliary passages they are represented by a hyperplasia of the glands, or the epithelial surface which becomes papillomatous. They are adenomas or papillomas. All benign tumors of the biliary passages, whatever their site, have two principal characteristics they are associated with a previous state of inflammation and they have a tendency toward transformation into cancer. According to Rolleston and McNe² the simple papilloma occasionally seen around the biliary papilla in the duodenum are growths of the intestinal surface of the papilla and not of the bile duct. Papilloma may however arise in the cavity of the ampulla of Vater.

The pre-operative diagnosis of benign tumor of the extrahepatic bile passages is probably never made. Carnot³ says "In the presence of jaundice which is at first intermittent and later continuous operation is always to be recommended. The diagnosis lies between biliary calculus and tumor of the ampulla of Vater. If the gall-bladder is large, it is more likely to be a tumor. If it is small and there is pain it is more likely to be a stone." When there are clinical signs of biliary obstruction and at operation the common duct is

found to be dilated it will be necessary for the operator to satisfy himself as to the presence or absence of a benign tumor of the common duct or ampulla of Vater. Even if a calculus is found, a benign tumor may be present (see Rolleston's case). If the presence of a tumor of the orifice is suspected it generally will be necessary to open the duodenum. Benign tumors may be removed by excision, curette or cautery and the prognosis may be excellent.

The following cases of benign tumors of the extrahepatic bile passages have been found in the literature

1. Lipoma, 1843, Bonisson. Inaugural Dissertation. Montpellier, page 137 (quoted by Konjetzny G. *Ergebn. d. allg. Path. u. path. Anat.* 1910, 21, 714.

2. Fibroma, 1863, Albert. *Atlas der path. Anat.*, IV. Bonn plate 38 (quoted by Konjetzny) Abts page 400. Involved wall of choledochus causing obstruction with icterus (von Karmann's case).

3. Lipoma, 1866, Wardell. *Lancet*, Lond. 1866, II, 407 (quoted by Konjetzny). At junction of common and cystic duct in a child of 3 years (Rolleston and McNe² think that this tumor may have been a papilloma which underwent myxomatous degeneration).

4. Polyp, 1880, Pond. *G. Gaz. med. (Ital-land)* (quoted by Konjetzny). Jaundice of 37 days duration disappeared with the passage of the polyp by rectum. Patient aged 40 years.

5. Polyp, 1884, Neumer. *Zschr. f. Klin. Med.* 1884, VII, 33. Neumer E. (quoted by Bazin). Patient aged 57 years. Jaundice. Mucosal polyp size of a pea, of common duct.

6. Papilloma, 1891, Jourdan. *Bull. Soc. anat. de Par.* (quoted by Konjetzny). Patient aged 48 years. Originated from cystic duct.

7. Papilloma (?) 1894, Chappet. *Lyon méd.*, 1894, June 3.

8. Papilloma, 1894, Rolleston, H.D. *Tr. Path. Soc. Lond.*, 1894, xiv, 83. In common duct near the site of a stone impaction.

9. Adenoma, 1895, Calavarra, C. *Arch. f. path. anat.*, etc., Berl., cxli, 221 (quoted by Konjetzny). Pure adenoma at orifice of common duct.

10. Myo-adenoma, 1895, Calavarra, C. *Arch. f. path. anat.*, etc., Berl., cxli, 3 (quoted by Konjetzny). Involved common bile duct.

11. Polyp, 1898, Monari, A. *Chir. méd. (Ital.)*, xxvii, 3 (quoted by Konjetzny). 3.5 centimeters above the ampulla.

12. Papilloma, 1899, McPhedra. *Sajous Annual*, 1899, IV, 423 (quoted by Rolleston and McNe²). Papillomatous growth around the duodenal orifice of the biliary papilla which gave rise to a suppurative cholangitis.

13. Lipoma, 1901 (?) Dickmann, J. *de méd. prat. de Montpellier* (quoted by Devic and Gallavardin *Rev. de méd.* 1901 xxi, 570). Common duct obliterated by lipomatous mass with icterus and large gall bladder.

35. Papilloma, 1929 Archibald E. W. Discussion of Bazin's paper at American Surg. Assn. March 1930.

Ann. Surg. xcli, 663. Patient aged 60 years. Intermittent jaundice and nausea. pure benign papilloma involving half of common duct at its opening successfully excised.

36. Papilloma, 1930, Barlow A. T. Ann. Surg. xcii 658. Benign papilloma of common duct attached by narrow pedicle removed surgically with portion of the duct.

37. Adenofibroma, 1931, Mayo, W. J. Quoted by Comfort and Walters. Ann. Surg., xciii 1144. (See also Marshall, J. M. Proc. Staff Meet. Mayo Clinic, 1931 vi 191). Two cases of adenofibroma of the stump of the cystic duct which produced intermittent obstructive jaundice with symptoms of cholangitis.

38. Neuroma, 1931 Comfort, M. W. and Walters W. Ann. Surg., xciii, 1142. (See also Walters, W., Priestley J. B. and Gray H. K. *Surg. Clin. N. America* xi, 821). Patient aged 55 years. Jaundice 2½ weeks. Neuroma 1 x 0.75 centimeters of middle portion of common duct. Successfully excised.

39. Papilloma 1931 Marshall. Proc. Staff Meet. Mayo Clinic, 1931 vi 191. Involved cystic duct.

40. Adenoma, 1931 Shapiro P. F. and Lifvendahl R. A. Ann. Surg. xciv 61. Patient aged 60 years had a ruptured gastric ulcer and died of bronchopneumonia. Adenoma attached to common hepatic duct. Caused no symptoms.

41. Neuroma, 1931 *Ibid.* Patient aged 59 years. Ampullation neuroma at stump of cystic duct.

In the following case there was an adenoma situated in the ampulla of Vater.

I. F. B. female aged 74 years, entered the Evanston Hospital on February 5, 1932. There was a history of severe abdominal pain and vomiting of 12 hours duration and a possible previous history of cholelithiasis. The pain was chiefly epigastric and somewhat more on the right. Two enemata were unsuccessful. There was marked rigidity of the upper half of the abdomen. The temperature was 97.5 degrees, the pulse 92, respirations 30, leucocyte count 20,750. The urine showed a faint trace of bile, a faint trace of albumin and rare red blood cells. Three hours after admission an exploratory laparotomy was done under ethylene anesthesia with the most probable diagnosis perforation of the gall bladder or stomach. Through a right paramedian incision the transverse colon and stomach were found to be normal to inspection and palpation. There was no evidence of tumor mass in any part of the abdomen which was carefully palpated. The only region which presented any pathology was the under surface of the liver. In this region there were old dense adhesions which completely covered the gall bladder and obscured it from view. The duodenum was adherent in this region. The gall bladder was finally exposed by careful tedious dissection of these adhesions. It was found to be about 2½ inches in length and presented two constrictions in its proximal half. By following down the cystic duct an enormously dilated common duct was disclosed. This structure was at first thought to be duodenum but dissection and aspiration insured its identification. The gall bladder was opened, four small gall stones were removed and drainage was instituted. The common duct was opened and a probe apparently passed into the duodenum over a roughened or somewhat obstructed part which seemed to be in the region of the ampulla of Vater. No stones were found in the common duct by the scope. In view of the advanced age of the patient and her condition on the operating table further exploration of the region of the ampulla of Vater was omitted. A T tube was sutured into the common duct and a single rubber tube was inserted in the gall bladder. A cigarette drain also was used.

Fig. Photomicrograph of adenoma of the ampulla of Vater. The darkly stained pancreatic tissue is seen in the lower half. The tumor is in the upper half projecting into the lumen of the common bile duct; a portion of the mucosa of which may be seen at the left.

The patient did very well after the operation except that the bile flowed externally instead of into the duodenum. Accordingly a second operation was done on February 24, 1932, 9 days after the first operation. At this operation a nigger was easily inserted into the common bile duct and with gentle pressure seemed to pass through the sphincter at the ampulla and enter the duodenum. A rubber catheter with extra holes in it was now placed in the common duct so that 4 or 5 inches of it protruded into the duodenum distally from the ampulla. This was anchored to the skin by silk suture. The common bile duct was closed around this suture and cigarette drains was placed. The patient went through this operation surprisingly well but bile continued to escape from the wound and none seemed to enter the bowel. Moreover duodenal contents escaped from the wound. After some 5 to 7 days the wound broke down and was opened widely. A fecal fistula, apparently originating from the colon, appeared on the fourteenth day. The patient became rapidly weaker and died the eighteenth day after the second operation.

A postmortem examination was made by Dr. F. D. Gunn, pathologist, Evanston Hospital, who discovered an enormously dilated common bile duct, the circumference of which was 6 centimeters, at the level of the fistula. The right hepatic duct had maximum circumference of 3 centimeters. His report continues as follows:

The gall bladder is shrunken down to the size of small pecan. There is a 3 millimeter sized opening in its fundus which is partly surrounded by fibrous adhesions. The mucosa of the gall bladder is pink and about 3 millimeters

in thickness. The lumen contains only a small amount of brownish mucus.

At its lower extremity the wall of the common duct is thickened and indurated. One 5 millimeter sized granular tumor-like nodule and several minute granules resembling granulation tissue project into and encroach upon the lumen. A 1 millimeter sized probe passes through the ampulla without forcing it. There is, also, a slit-like opening admitting the tip of the little finger which leads from the lowermost portion of the dilated segment of the common duct (about 1 centimeter from the ampulla) into the duodenum. At a distance of about 1 centimeter distal to the ampulla, there is a lentil-sized nodule beneath the mucosa of the medial wall of the duodenum.

Microscopic findings. Ampulla of Vater: The granular mass which was found projecting into the lumen of the common bile duct at the ampulla is composed of a mass of gland like epithelial structures embedded in dense fibrous tissue and smooth muscle. They differ strikingly from the Brunner's glands, near which they lie, in that they are much simpler, more like embryonal structures and consist mainly of simple or branching tubules. A few of them show cystic dilatation, proliferation and desquamation of their columnar epithelium. No definite malignant changes are observed. The fibrous stroma is lightly infiltrated with lymphoid cells and eosinophils. The overlying duodenal mucosa shows postmortem distention. A similar destruction of the lining of the ampulla is apparent.

Anatomical diagnosis. Chronically inflamed adenoma of the ampulla of Vater with stenosis of the lumen of the common bile duct. High grade dilatation of the common bile duct and of the hepatic ducts. Chronic fibrous cholecystitis with contraction of the gall bladder. Recent surgical wound of the upper part of the abdominal wall (right rectus incision). Small surgical fistula between the fundus of the gall bladder and the floor of the abdominal wound. Surgical fistula of the common bile duct opening into the floor of the abdominal wound. Adenoma of the duodenal mucosa. Fatty infiltration of the pancreas. Brown atrophy of the heart. Hypostatic congestion and early lobular pneumonia of both lower pulmonary lobes. Small adenoma of the cortex of the left kidney.

SUMMARY

1. A case of adenoma of the ampulla of Vater is reported.

2. A review of the literature of benign tumors of the extrahepatic biliary passages is presented.

CONGENITAL HYPERTROPHIC STENOSIS OF THE PYLORUS

A STUDY OF FOUR HUNDRED AND TWENTY FIVE CASES TREATED BY PYLOROMYOTOMY¹

THOMAS H. LANMAN, M.D., F.A.C.S., AND PATRICK J. MAHONEY, M.D., BOSTON

TO justify surgical measures for the relief of any condition certain facts must be established. First and most important can these surgical measures be made safe enough to justify the risk, not only of the operation itself but of the incidental dangers attendant on any major surgical procedure? Second are the end results of such surgical measures satisfactory?

In this hospital the surgical treatment of congenital hypertrophic stenosis of the pylorus has for many years been regarded as the treatment of choice. This series of 425 cases covers the period from 1915 to 1931. In all cases pyloromyotomy (Fredet-Rammstedt type) has been employed. Study of the results in this series establishes the safety of surgical treatment and also the fact that there is prompt and lasting relief of symptoms. The factors that we have found to be of importance in minimizing the mortality are emphasized.

MORTALITY

In Table I the total mortality in the series is shown to be 6.3 per cent. Of greater interest however, is the reduction in mortality from 10.4 per cent in the first 125 cases to 7 per cent in the next 150 cases and in the last 150 cases a further reduction to only 2 per cent. From the early part of 1930 up to the present time, June 1932, there have been no deaths.

The measures that have made possible this reduction in mortality have to do almost entirely with the differences between the surgical treatment of the small patient and the adult. In infancy or childhood all surgical procedures carry much higher proportionate risk both operative and incidental. In congenital pyloric stenosis the technical difficulties of the operation itself are few and in competent hands should be as slight as in any abdominal operation. Indeed the apparent simplicity of this operation has been the source of considerable danger to these patients for as Barrington Ward states in the preface to his *Abdominal Surgery of Children*: "The adult may be safely treated as a child but the converse can lead to disaster."

The causes of death in this series are included in two main groups. In the first group are those incident to the technique of the operation itself

and include operative and postoperative hemorrhage, wound infection and peritonitis. In the second group are those causes due to the undernourished and dehydrated condition of the patient which adds to the danger of postoperative shock and collapse. A predisposing factor to infection and leads to unsatisfactory healing of the wound. Such a condition also makes difficult the postoperative establishment and maintenance of the adequate nutritional and fluid needs of the patient.

In the operation itself extreme care must be observed that all hemorrhage in the abdominal wall incision be absolutely controlled. A right rectus muscle splitting incision about 2 inches long with its midpoint at the edge of the liver is used. The liver edge is the important landmark, not the costal margin. In making the incision in the pylorus the bloodless area is selected. The upper and posterior surface of the pylorus is the point at which there is the least blood supply. The pylorus must be delivered into the wound and its upper and posterior surface rotated outward and slightly downward to expose this area for incision.

Hæmorrhage from the pyloric incision is usually slight and is easily controlled by hot saline packs. If not controlled by these means the bleeding point must be sutured with fine silk on a non-cutting needle. A clamp or tie will usually cut through the rather hard and friable tissues. If suture does not control the bleeding a piece of the rectus muscle should be sutured over the bleeding points. The greater incidence of hæmorrhage from the pyloric incision in patients over 6 weeks of age has been an interesting observation in this series and will be considered in greater detail in a later paragraph.

Peritonitis may result more often from an operative perforation of the duodenum than from

TABLE I.—SUMMARY OF CASES

Years	Serial number	Number of cases	Deaths	Mortality per cent
1915-1923	1-125	125	13	10.4
1923-1928	125-275	150	11	7.0
1928-1931	275-425	150	3	2.0

Chart 1. Age at which hospitalization began.

a break in aseptic technique. The greatest care is necessary in making the incision at the duodenal end of the hypertrophied pylorus. It is here that the hypertrophied pylorus terminates abruptly at the duodenum which is extremely thin. Perforation of the duodenum is easy but avoidable. If perforated, the hole in the bowel wall should be closed at once with a silk stitch. In this series, the duodenum was perforated three times but in only one case was there a fatal peritonitis. Peritonitis may also be the result of operating near or through an infected field. In one case in this series there appeared to be a definite relation between an omphalitis and a later postoperative peritonitis. Peritonitis may also be a metastatic affair the result of a bacteremia or septicemia, secondary to other foci of infection, usually an upper respiratory infection. In 2 cases in this series, a peritonitis occurred in poorly nourished infants from 16 to 30 days after pyloromyotomy, despite the fact that vomiting had ceased. The peritonitis was undoubtedly a metastatic one.

The lowered resistance and resulting diminished power of healing in these patients requires the most rigid asepsis and hemostasis, also the most meticulous care in approximating the abdominal incision layer by layer. Postoperative evisceration following delayed healing due to imperfect approximation, low grade infection, hematoma, or combination of any or all of these factors may occur. In this series, in 3 cases, the incision reopened on the fifth to the seventh day. There

were 2 deaths. Deaths due to operative peritonitis, hemorrhage, evisceration are largely preventable and in our series accounted for 6 or 22 per cent of the total mortality. The remaining deaths were classified under such headings as malnutrition, "collapse" and acute nutritional disturbance. The causative factor in a large majority of these cases was the patient's undernourished and dehydrated condition, and the inadequate measures taken to combat it, both before, during, and after the operation. Important as is the proper operative technique, the adequate pre-operative and postoperative care is even of greater importance in reducing the mortality rate. Seventy-eight per cent of our total deaths were due to causes other than faulty operative technique.

The steady decrease in our mortality rate has been concomitant with a longer pre-operative stay in the hospital. This longer pre-operative stay is not inclusive of the period of observation that certain cases received before diagnosis was established. The longer pre-operative period represents the time spent in overcoming the dehydration of these patients.

THE PRE-OPERATIVE CARE

Pre-operative care must be based on reason and not on any routine procedure. The operation is not an emergency. Where early diagnosis is made much less in the way of pre-operative care is required. However in the majority of these patients, vomiting has caused a loss in body fluids and has caused a loss in blood chlorides, which may result in alkyllosis. The starvation incidental to prolonged vomiting has caused a depletion of the glycogen reserve in the body with its resulting ketosis.

Dehydration must be combated by salt solution given by hypodermoclysis. This supplies fluid for the depleted body tissues and aids in the restoration of electrolytes lost by persistent vomiting. Intravenous administration of glucose solution while not providing directly for the loss of body fluids, does account for the removal of ketone acids, and promotes re-establishment of renal function. At this hospital it is usual to give 10 per cent glucose solution intravenously and normal saline by hypodermoclysis. In the extremely cachectic patients we give in addition a blood transfusion, 10 cubic centimeters per pound of body weight. Blood transfusion is now found advisable in only about 5 per cent of the patients treated. Twenty-four to forty-eight hours is time well spent in combating dehydration before operation.

Next in importance is the prevention of loss of body heat. Exposure contributes proportionately more to operative shock than in older patients. The field of operation exposed though actually small, is proportionately a much greater surface area than in adults. The patient is placed on warm blankets beneath which some form of heat may be constantly applied. The legs, arms and chest should be wrapped in flannel bandages.

POSTOPERATIVE CARE

After operation the infant should be immediately dried and redressed in warm coverings and the body heat constantly maintained. The postoperative feedings by mouth cannot at first be sufficient to meet either the caloric or fluid needs as the effects of dehydration may still be present. The following method has proved effective in our hands.

2 hours following operation, 1 ounce of sterile water
2 hours later 1 ounce of sterile water
2 hours later 1 ounce of whey Repeat at 2 hourly intervals for 3 feedings.
2 hours later $\frac{1}{2}$ ounce of whey and $\frac{1}{4}$ ounce of breast milk.

Repeat for 3 more feedings. Then decrease whey by 1 dram for each feeding and increase breast milk by 1 dram until whole breast milk is taken.—1 ounce.

Breast milk is then increased by dram amounts each 2 hours until such time as the patient is getting 1½ ounces each feeding. The next procedure is to lengthen the interval and increase the amount, and finally to change to a modified milk formula if the mother's milk is not available.

(A suitable breast milk substitute is used from the start if breast milk is not obtainable.)

This schedule of feeding by mouth does not meet either the caloric or fluid needs of the infant for the first few days. It is unwise in the usual case to attempt to meet them by feeding by mouth before the fifth day after operation. It is, therefore necessary and most important during this period, to supplement the oral intake of fluids by rectal taps, hypodermoclysis of salt solution, or the administration of intravenous glucose. The infant should receive and retain 3 ounces of fluid per pound of body weight each 24 hours, and the chloride and glucose requirements of the individual patient must be met. In this series, 5 of the 27 deaths were attributable to faulty operative technique. This number should, of course, be still further reduced until the irreducible minimum be reached beyond which the human element cannot go. In the private practice of the staff the mortality is negligible. In a hospital series, the poor risks are always present and their number will decrease

only as a greater number of cases are recognized early and proper treatment instituted. But there is great need of recognizing that the poor operative risks can be brought into much better condition to withstand surgery than was formerly the case.

Our reduction in mortality from 10.2 per cent in 1915 to 1923, to 2 per cent in 1928 to 1931 was not entirely due to more skilled and experienced operators but rather to better pre-operative and postoperative care. There was only one operative death in which the operator had had only small operative experience in these cases—death in this case being due to hemorrhage from the pylorus.

ANÆSTHESIA

Ether given by the open drop method seems to us the anæsthetic of choice. Gas and oxygen avertin, supplemented by gas and oxygen, or ether all have their place. Novocain alone has not been used in this clinic for 4 or 5 years. It adds to the risk by prolonging the time of operation and may interfere with healing of the wound. Ether was used in 98 per cent of the patients in this series. In no instance did death occur on the table, nor was there any postoperative complication that could be directly traced to this anæsthetic.

Of the 27 deaths in this series, 9, or 33½ per cent occurred in patients under 6 weeks of age. There were 294 cases or 69 per cent of the series in which operation was done before the patients were 6 weeks of age. This gives a mortality of 3 per cent in the younger group. Eighteen deaths or 66.6 per cent of the total mortality, occurred in the group of patients who were over 6 weeks of age. This gives a mortality of 13.7 per cent for the 131 cases in the older group. In addition to carrying a much higher mortality, this group also includes a large number of cases in which hemorrhage from the pyloric incision was greater in amount and often required additional measures for its control.

In none of our cases was there any doubt as to the existence of a true hypertrophy of the pyloric fibers, but it was very noticeable that the older patients who had had a longer period of symptomatology did present a more vascular pyloric ring. A higher mortality in the older age group has been noted by other writers. It is our belief that the greater vascularity of the pyloric ring may be due to a superimposed element of pylorospasm which although present to some degree in all cases is increased as a result of prolonged symptomatology. When true hypertrophy of the pyloric ring is present, medical measures will

not effect as safe and as prompt a cure as pyloromyotomy. The greater morbidity and mortality in this older group plus the fact that all of them had a true hypertrophic stenosis convinces us that early surgical treatment should be instituted, that it will carry less danger to the patient, and result in quicker relief of symptoms.

RELIEF OF SYMPTOMS

In practically all cases relief of symptoms has been prompt and lasting. We have been able to observe a sufficient number of cases over periods of 4 to 12 years to feel sure of this fact. In 2 cases a secondary operation was done because of persistence of symptoms. One of these had been operated upon previously at another hospital. The findings at this second operation revealed that the section of the constricting fibers was not complete. Re-incision throughout the entire length of the pylorus resulted in cure. In the other case there was apparently an incomplete division of the pyloric fibers. Symptoms had persisted and secondary operation 6 weeks later was unsuccessful the patient dying 4 days after operation following eversion. We have been able to observe the pyloric ring in cases in which death from other causes occurred 2 months to 7 years after pyloromyotomy. In all cases an apparently normal pylorus was present.

SIGNS AND SYMPTOMS

Chart I shows the age at which hospitalization began. Sixty nine per cent were 6 weeks or younger with the peak at 4 weeks. The proportion of males to females was 84.7 per cent to 15.3 per cent.

The five major signs and symptoms were

1. Failure to gain in the absence of fever or other signs of infection.
2. Persistent vomiting of the projectile type, occurring shortly after feeding the vomitus consisting of stomach contents never bile stained.
3. Visible gastric peristalsis moving from left to right.
4. Scanty stools.
5. A palpable pyloric tumor.

Other signs and symptoms observed in many cases, and which confirm rather than establish the diagnosis, are (a) loss of fatty tissue, (b) dehydration, (c) ketosis (acetone breath and acetone in urine) (d) alkalosis (tendency toward hypertonicity and gastric tetany) (e) fullness of epigastrium (due to hypertrophy of stomach musculature and dilatation of the stomach), (f) flatness of hypogastrium (due to failure of food to pass through the pylorus) (g) diarrhea. In

13 per cent of the case histories, diarrhea was emphasized to a greater extent than scanty stools (frequently inaccurately referred to as constipation). The reason for the diarrhea was usually obtained from careful study of the case history. Multiple forms of cathartics and enemas had been given to cure the patient of "constipation." In addition there may be the diarrhea associated with starvation, the stools being composed of intestinal secretions.

The five major signs and symptoms have been observed prior to operation in all of the last 200 patients treated at the Children's Hospital. In only 1 case was the diagnosis not confirmed at operation.

The information from the barium meal roentgenogram shows the amount of food that passes through the pylorus and the rapidity of emptying of the stomach. It is possible to obtain this information, though not so promptly by a study of the amount of feces passed by rectum. The presence of barium in the stomach at the time of operation adds to the technical difficulties of operation. We now place less reliance on the shape of the stomach as shown by the roentgenogram in making a diagnosis than formerly. In the last 200 patients, the roentgenogram has been used in only 16 cases.

ETIOLOGY

We have no satisfactory theory as to the etiology of congenital hypertrophic stenosis of the pylorus. We found no evidence supporting the theory that injury to the central nervous system during birth may be an etiological factor. We found no suggestive association between this disease and such conditions as megaloureter or Hirschsprung's disease. There is no racial predisposition to this disease. Vitamine deficiency in the diet is apparently not a causative factor in this disease. We found no proof for the theory that the condition occurs more often in the first born. The occurrence of these symptoms in the first born is not in itself of especial diagnostic significance.

SUMMARY

Analysis of the 425 cases establishes the safety of surgical treatment of pyloric stenosis. Because the mortality and morbidity is greater in the age group of 6 weeks and over who have had longer duration of symptoms and treatment, we advise operation as soon as the diagnosis is established. The shorter the period of symptomatology the better is the operative risk. The safety of surgical treatment of pyloric stenosis is dependent on the close observance of many details. This includes

1 Combating and overcoming the loss of body fluids before and after operation. The measures to be used are dependent on the degree of dehydration the degree of dehydration will be greater in cases having a longer duration of symptoms.

2 Especial care in preventing loss of body heat before during and after operation

3 The greatest care in controlling hemorrhage at operation. Rigid asepsis and painstaking approximation of the abdominal wound

4. Incision in the "bloodless" area of the pylorus being sure that all constricting fibers are divided but using especial care not to perforate the mucosa of the pylorus at the duodenal end. It is safer to use blunt dissection in completing the division and spreading of the serous and muscular coats.

5 Hemorrhage from the pyloric incision not controlled by hot saline packs must be controlled by suture with or without using a piece of rectus muscle

6 The care during the first 4 or 5 days following operation must include the maintenance of the fluid requirements by methods supplementary to what can be administered by mouth. The caloric needs usually cannot be met for these first 4 or 5 days following operation and it is unwise to attempt to do so. If the fluid requirements 3 ounces per pound of body weight are met the caloric intake is of minor importance during this short period

7 We believe that ether by open drop method is the best and safest anæsthetic

CONCLUSION

We believe that pyloromyotomy is the treatment of choice in congenital hypertrophic stenosis of the pylorus. This surgical treatment can and should be made safe enough to warrant its use in all cases. We believe that pyloromyotomy should be advised when the diagnosis is established and that it offers safe sure prompt and lasting relief of symptoms.

EARLY DIAGNOSIS OF CARCINOMA OF THE CERVIX

DR. WALTER SCHILLER, VIENNA, AUSTRIA

II Gynecological Clinic, University of Vienna

AT present there are only two valuable methods of treating carcinoma—by operation and by radiation therapy. All attempts at serological, pharmacological or dietetic treatment have so far proved to be of no practical value and have resulted in failures. It is rather doubtful, therefore, whether with present facilities of investigation, better results can be expected in the near future.

Of the two practical and valuable methods, the surgical treatment, at least as far as the gynecology is concerned, seems to have reached a point where no further improvement can be expected. Any changes in operative technique made in the last few years are simply modifications of well known methods. The technique of applying radiation in carcinoma of the uterus seems almost to have reached a similar stage. It is true that in the last few years some modifications have been made but it would seem that progress can be expected only from the physicists through the invention or discovery of new tubes and rays, for the radiologist now makes the best possible use of the instruments which have been given to him by the physicist.

Early diagnosis and treatment are the only and the best means we have today of improving the results in the treatment of carcinoma. There is no doubt that early operation and the application of radiological measures before the wide extension of the cancer decidedly improves the prognosis. If the carcinoma is internal and therefore cannot be seen, early diagnosis is difficult and probably depends upon some general reaction yet to be discovered, the presence of which may be revealed by examination of the blood, urine, serum or skin. Of course if diagnosis were thus possible it would still be very difficult to find the site of the tumor. At the present moment, in spite of the high standard attained in the study of cancer we are far from reaching this goal. Somewhat more favorable are the possibilities of detecting carcinoma of the epithelium in areas readily examined with the eye as for instance the skin, mouth, penis, vagina, cervix. In any case the main thing is to be able to make diagnosis during the earliest stage; this can be done only if patient comes for consultation during this stage.

The laboratory of our clinic, following the example of Wertheim, Schottlander and Ker-

mauer is making a most intensive study of carcinoma of the cervix and for some years we have been making extensive examinations in an effort to make a diagnosis in the early stage of carcinoma of the cervix. The first condition necessary in making such a diagnosis is to obtain data as to the appearance peculiar to the growth in the earliest stages. My first work, therefore, was devoted to discovering this information. The work was simplified by the fact that the area of predilection for carcinoma of the cervix is the region near the external os. Thus I was very likely to find data in a systematic examination of some 100 or 1000 uteri. As a matter of routine I have for several years examined under a microscope cross sections of the cervix of each uterus removed at our clinic for any reason, for example fibroids, inflammatory tumors of the adnexa, inflammation of tubes, neoplasm of ovaries, etc. I have thus succeeded in securing data as to the histological pictures presented in the early stages of the carcinoma of cervix. It must be clearly understood that these histological findings, which I can describe morphologically quite precisely, really represent the earliest stages of a carcinoma which, if not removed, would have developed into the more advanced type of carcinoma of cervix. This would be easy to prove if the early cancer were a miniature of a developed carcinoma just as a young mouse 3 weeks old is a miniature of an old one; consideration of course being given to the difference in size. The scientist as well as a person not familiar with science who has no knowledge about mice would conclude from morphological similarity that the grown up mouse develops from the young one. The evidence is more difficult if the early stages are morphologically different from the final stage. There is no morphological similarity between a 10 day old embryo of a mouse and a newborn mouse and the common sense upon which many biologists think they can rely is missing. Direct observation is not readily possible either as we cannot observe the embryo's development into a mouse. The evidence that the embryo is the first link in the development of a newborn mouse can only be secured through a series of microscopic pictures to include the whole evolution with the intermediate stages. These changes are not accessible under direct observation, but it is possible to

At the upper border of the section the carcinomatous border passes sharply into normal epithelium. The thin line here and in the following illustrations marks the superficial extension of carcinoma. (X20) B Transition of carcinoma and normal epithelium highly magnified. (X50.) C, Another marginal portion of the same carcinoma with characteristic sharp and sloping transition. (X15) D The same transition highly magnified. In the characteristic way the carcinoma appears further in the deep layers and the normal epithelium in the superficial layers. (X50.)

secure a complete series of slides showing intra uterine development. This method, the foundation of embryological research can be applied as well to the development of carcinoma. The prevailing opinion as to carcinoma is based upon a study of carcinoma in the advanced stage at which time it has become superficially ulcerated and penetrates deep into the organs, and this picture has remained with us since before microscopic research was known. The microscope

however revealed further characteristics, namely atypism and polymorphism in short the irregularity of cells. I am going to attempt to show that in the earliest stages of carcinoma the microscopic features mentioned are found instead of the older macroscopic characteristics.

For didactic reasons I shall not begin with the smallest carcinoma but with the type of carcinoma which has been diagnosed clinically for many years and has been accepted as such, in other

Fig. 2A.

Fig. 2 Case No. 185 a. A, Advanced solid carcinoma of the cervix, marginal part. Normal epithelium to both sides of the fornix. Between the carcinoma and the normal epithelium there is a small and short carcinomatous layer which is smaller than the normal epithelium and from which it is sharply separated. It forms characteristic blunt mushroom-like projections which do not grow deeply ($\times 18$) B, The short carcinomatous border layer with round epithelium projections and the sharp transition in comparison to the normal epithelium highly magnified ($\times 57$) C, Carcinomatous epithelium from the border layer ($\times 475$) D, Carcinomatous epithelium from the downgrowth of a deeply penetrated carcinoma. The histological picture shows the absolute similarity to the carcinomatous layer in B ($\times 475$)

words, the carcinoma upon which our ideas of this growth have been founded. An examination of the region immediately surrounding a large carcinoma of the cervix reveals that in most of the cases the growth is separated from the normal epithelium by a small inflammatory zone free of

epithelium. Wherever the carcinoma penetrates from the surface into normal tissue there is present a narrow zone with inflammatory infiltrated connective tissue not covered with epithelium or with cancer. Although in a small percentage of cases the carcinoma is in direct junction with the surrounding normal epithelium (so that the normal epithelium does not project over the downgrowth) the carcinoma forms a surrounding superficial layer of about the same depth as the normal epithelium and, as I have always found, definitely marked off as though the area had been outlined with a ruler. Schottlaender and Kermauner were the first to notice the superficial narrow layer. They called it the carcinomatous superficial layer. While they mention only a few cases, in my systematic examinations I have found a great number of cases presenting these carcinomatous layers. When examining carefully I have also found that when in one spot carcinoma is marked off from normal tissue by a zone free of epithelium the growth is usually wholly surrounded by such a zone free of epithelium, and if there is a carcinomatous layer in one place the growth is always completely surrounded by such a carcinomatous layer. Obviously the kind of demarcation does not depend on local circumstances but rather on the biological nature of the carcinoma and of the organism in which carcinoma develops.

The question arises. Is this carcinomatous layer really a part of the carcinoma? On the basis of the characteristics of advanced carcinoma the answer must be in the negative, for the carcinomatous layer is neither superficially ulcerated nor does it invade the deeper tissue. Neither does it meet a further requirement: the layer is definitely marked off from the connective tissue and does not show any tendency to penetrate deeply neither by single cells nor by groups of cells. From the old and antiquated point of

Fig. 2B

Fig. 2C.

Fig. 2D

Fig. 3 Diagram of the development of a carcinoma of the squamous epithelium of the cervix. A Advanced downgrowth, superficial ulceration, carcinomatous superficial layer. B Downgrowth and superficial layer. C Beginning downgrowth and superficial layer. D Superficial

layer only which means change of superficial squamous epithelium next the external os into the carcinomatous type. The carcinoma begins to develop as shown in D and progresses as shown in C, B and A.

view carcinoma is diagnosed only when it penetrates deeply and then the carcinomatous layer is separated from the carcinoma and is considered a surrounding region, not a carcinomatous zone. From the histological point of view however this hypothesis is altogether wrong because the layer shows the characteristics of carcinoma atypical and polymorphous cells and frequently plenty of mitotic figures. In addition there is no histological difference whatsoever in the area where the carcinomatous zone passes into the deeply penetrating carcinoma while there is a distinct histological difference at the point where the carcinomatous layer is marked off from the epithelium. We must of necessity therefore consider the carcinomatous layer as part of the carcinoma (Figs 1-2). In my systematic examinations I have found carcinomata in which the proportions of the downgrowth and the superficial carcinomatous layer were in inverse relationship to the usual proportion in advanced carcinomata in which the downgrowth is the paramount part while the carcinomatous layer is but a small area surrounding it. The amount of downgrowth is several hundred times as great as the superficial layers. In some of the smaller carcinomata however the proportion is reversed. The carcinomatous layer is larger and in the slide frequently covers half the cervix occasionally extending to the fornix while the deeply penetrating parts consist of but a few relatively small downgrowths showing only very shallow superficial ulceration. In the next type we find a somewhat smaller carcinomatous layer with only 2 or 3 downgrowths at the external os, yet with no ulceration. In still a younger type there is but one small short downgrowth and no superficial ulceration. In the last and youngest type are the cases which have only a carcinomatous layer and no deep penetration, downgrowth at the external os, or ulceration.

The cases presenting the very small carcinomatous layer with no deep penetration or ulceration formed part of the material for my histological examinations. A study was made of cases presenting all of the intermediate stages from the beginning penetration at the external os, the progressing downgrowth with ulceration at the external os, up to and including the large advanced carcinomata which completely infiltrate the collum and are superficially ulcerating crateriform growths (Fig. 3). If the carcinomatous area bordering the carcinoma is recognized as carcinoma and we are logically bound to accept this assumption as true then from our study of the uninterrupted series the smallest carcinomatous layers with no downgrowth must be considered as carcinoma as well. That is a picture of the youngest stage of carcinoma that we are able to recognize at the present moment. These smallest of carcinomata which include the last cases in our histological collection are 2 to 3 millimeters in diameter sections of epithelium at the external os the epithelium through changes in its cells to polymorphic and atypical types becoming characteristic of the carcinomatous layer.

In this early type there is no downgrowth or metastasis—two phases in the development of carcinoma. Downgrowth is bound to develop sometimes it appears early, but sometimes it may not appear for months and years. The same is true as to the early and late appearance of metastases. It must be emphasized however, that the presence of carcinoma is not synonymous with downgrowth—there is an early stage of carcinoma in which are present certain tissue changes characteristic of this stage of development for instance the cell changes the appearance of atypical and polymorphic cells—but the growth has not begun to penetrate the deeper tissue.

Fig. 4A.

Fig. 4. Case No. 25623. A, Commencing carcinoma of squamous epithelium at the external or not penetrating deeply yet. The carcinoma appeared over the region of healed cystic erosion ($\times 15$). B, Carcinomatous tissue from the layer highly magnified. ($\times 475$.)

The objection that the carcinomatous layer is not carcinoma because it does not penetrate deeply is equivalent to saying that the embryo of a mouse has not the characteristic features of a mouse because the embryo does not breathe through its lungs as a grownup mouse does. Breathing through the lungs is a postnatal characteristic of the mouse while the properties of a mouse are inherent in the embryo.

The term "precancerous" for carcinomatous layers seems to carry two different meanings: some authors use the term "precancerous" to designate a growth which may become a carcinoma while others use the term in reference to a growth which is bound to become carcinoma. As long as the term "precancerous" has more than one meaning it should be avoided. The study of our uninterrupted series would indicate that a carcinomatous layer may represent two things: either the borderline of an advanced carcinoma—in which case it is senseless to call it anything

Fig. 5A.

Fig. 5. Case No. 7706. A, Commencing carcinoma consisting of an extended superficial layer which has penetrated deeply in one place only. The deepest part lies $1\frac{1}{2}$ millimeters from the surface. ($\times 5$). B, Carcinomatous layer highly magnified. ($\times 67$). C, The region of deep penetration highly magnified. ($\times 90$.)

else but cancerous—or the early stage of carcinoma which later on will penetrate deeply. In this case too it is better to use the term of "young carcinoma" or early stage of carcinoma, instead of the ambiguous term "precancerous." Our experience has demonstrated that the smallest carcinomatous layer without downgrowth will later if allowed to grow develop into a deeply penetrating carcinoma and eventually ulcerate superficially. We do not speak of a "prehuman embryo" but of a "human" embryo and I believe the same thing applies to cancer: there is a "carcinomatous layer" but not a "precancerous layer."

Fig. 4B.

Fig. 5B.

Fig. 5C.

Fig 6A

Fig 6B

Fig 6C

Fig 6 Case No. 1904. A Early commencing carcinoma of the cervix consisting of a larger superficial layer and two small projections in the region of the external os. The section shows the characteristic carcinomatous superficial layer and its separation from the normal epithelium

to the right. (X20.) B Two small projections dip deeply into the region of the external os with strong inflammatory infiltration of the surrounding tissue (X40.) C Tissue from the carcinomatous layer highly magnified. Atypical mitotic figures, atypical nuclei (X45.)

The histological characteristic of this carcinomatous layer has already been mentioned polymorphic and atypical cells especially as regards the nuclei. Large nuclei may be surrounded by small ones dark nuclei may be next to light nuclei and occasionally giant cells may be found with several nuclei in one cell. The great number of nuclei is extraordinary there being more nuclei than in the healthy epithelium. The regular order as seen in normal epithelium is absent. In healthy epithelium the number of nuclei diminishes centrifugally from basal layer to the surface, until in the superficial layers only a few shrunken nuclei living in large cell alveoli are found. In the presence of a carcinomatous layer however we find on the surface a great number of dark nuclei lying close to one another. The basal layer is sharply demarcated against the under

lying connective tissue and never shows projecting single cells or groups of cells. This is no counterevidence against the carcinomatous character of the epithelium. In advanced carcinomata of great maturity the projections in the depth of tissue with sharply defined basal cell layer are regularly seen (Fig 7). The division and separation into basal layer prickly-cell layer superficial vesicular parakeratotic layer are abolished. Occasionally however we can still find remnants of the former epithelial differentiation in carcinomatous epithelium. Just as there are hornifying carcinomata of the skin and the ability of the normal skin to become horny is still preserved and just as there are carcinomata of the mucous membrane and the function of the normal gland is preserved (the pathologist calls them carcinomata of very advanced maturity or of great dif

Fig. 9A

Fig. 9 Case No. 27027 A. Commencing carcinoma of the squamous epithelium of the cervix which led to an inoperable reappearance in spite of a hysterectomy. The carcinoma consists of a small superficial layer with only little downgrowth along the cervical glands in the cervical canal. In spite of an operation the tumor reappeared and was inoperable ($\times 5$). B. Transition in respect to normal epithelium, highly magnified ($\times 57$). C. The carcinomatous layer highly magnified. ($\times 15$) D. Beginning of the deep penetration along the cervical glands, highly magnified. ($\times 60$).

ferentiation) there are also carcinomatous layers still showing a distinct basal or parakeratotic layers on the surface, certain rests of differentiation. Such remnants of potency of differentiation do not contra indicate the carcinomatous nature of the layer. The demarcation between the carcinomatous layer and the normal epithelium is always distinct, so that it is possible to indicate the exact point to which the carcinoma reaches and where the normal tissue commences. Areas of transition are nowhere to be found, nor are there transitory cells in contradiction to this fact are the hornifying carcinomata of the vulva and

of the skin in which there is no distinct demarcation between carcinomatous and normal tissue, obviously on account of the great maturity of tissue. Occasionally we can see within the normal tissue near the borderline single dark cells which, from a morphological standpoint, are characteristic of carcinomata. The line of demarcation is always oblique and always proceeds so that, in the basal part of the growth, it reaches farther than the normal epithelium does on the surface, i.e. the carcinomatous layer is wider at the base than on the surface. A further characteristic of carcinomatous epithelium is that the superficial layer which in normal epithelium consists of large vesicular light cells with small shrunken nuclei or rests of nuclei is missing. This superficial layer which is typical in the epithelium of the cervix—normally the epithelium of the cervix does not show parakeratosis—is filled with glycogen as proved by staining (Fig. 8). As Schaffer pointed out the squamous epithelium undergoing differentiation may be transformed into horn or it may gather glycogen. In the epithelium of the cervix the latter property is characteristic, and the glycogen disappears when the epithelium becomes a carcinomatous layer. This is true not only for the superficial layer of the epithelium of the cervix downgrowths and extension of epithelium too are free of glycogen. This glycogen is not soluble in water. It is called glycogen of the epithelium and should not be mistaken for the glycogen of the liver and muscles which glycogen is soluble in water. The insoluble glycogen of the epithelium can be stained according to Best on slides which have been washed in running water for hours. Occasionally soluble glycogen is found in carcinomata of the collum characterized histologically by large light vesicular cells. Lahm, Babes and Lazarescu-Pantzu have described such cases, which are rare and in which the glycogen is very different from the cervical epithelial glycogen.

In consequence of shrinkage caused by fixation in formalin the carcinoma appears retracted in the cervical canal. ($\times 0.8$.)

A further evidence that the carcinomatous layers are actually carcinoma is to be seen in similar diagnoses in the skin. To Bowen belongs the credit of discovering and describing such findings in relation to the skin. He was the first to notice the changes in the epithelium which are characterized by polymorphic and atypical cells, great numbers of cells and nuclei, and the clump-

ing cells without downgrowth. Because he found no downgrowths Bowen described the cases as being specific precancerous and so the condition became known as Bowen's precancerous dermatosis. Subsequent controls confirmed Bowen's diagnoses. After prolonged observation, however, Bowen found that downgrowth began to develop, i.e. the dermatosis became a true carcinoma of

Fig. 11A.

Fig. 11B

Fig. 11C.

Fig. Case No. 27-03. A, Scraping of the iodine negative area. A typical polymorphic epithelium with downgrowing projection which was diagnosed as carcinoma ($\times 67$). B, A beginning carcinoma of squamous epithelium at the external os. On the left is shown the inflammatory infiltration of the cervical tissue on the

right in the upper corner of the section a carcinomatous layer with a sharply defined demarcation. Two superficially placed projections are seen below the sharp border. The larger one has a triangular form with a space in the center ($\times 15$). C, The transition strongly irregularized. ($\times 57$)

the skin. This transition took place after a few months in some cases after a few years, so that the hypothesis was accepted that Bowen's dermatosis was only a special form of carcinoma of the skin different from the other forms only in the extraordinarily long interval between development on the surface and in the deeper tissue, it was the Dutch dermatologist Caroll who laid down that idea most precisely. Bowen's dermatosis, that is, the form of carcinoma of the skin discovered by Bowen, commences its growth as a superficial layer but does not affect the deeper tissues. It refutes, too, as do our diagnoses as to the cervix Ribbert's theory that carcinoma originating from epithelium misplaced in the deep initiates in the deep. Histologically and cytologically Bowen's dermatosis corresponds with our diagnoses of the cervix.

A further evidence that these smallest carcinomata really are carcinomata is to be found in the fortunately rare clinical failures. A report of a characteristic case of this kind follows.

A woman, aged 46 years, was operated upon on account of tumors of the adnexa, and a hysterectomy was done. The cervix seemed quite smooth, showed no suspicion of cancer and macroscopic examination showed no erosion. I must add that this patient was examined and operated on in 1927 at which time we had formulated no special method for the early diagnosis of carcinoma of the cervix and had not attained sufficient experience to determine the histological aspect of the early stages. After systematic examination of the cervix a typical polymorphic celled, carcinomatous layer was discovered, with distinct demarcation and free from glycogen. Within the cervical canal two small areas were noted in which the growth had begun to penetrate the deeper tissue. The wound healed by first intention and the patient was discharged from the hospital after she had been given a short course of treatment for

slight bladder trouble. She was free from complications for a long time, but after 4 years she returned to our clinic with the typical neuritic pains in both legs and a carcinoma, almost the size of a fist, located in the small pelvis which could be easily palpated. In spite of total extirpation there probably was already formed a very small metastatic growth which caused the reappearance. Had we been able to diagnose carcinoma with certainty 4 years previously, the parametria would have been removed as well by Wertheim's method and the patient would have been given strong radiation after treatment.

This case is strong evidence of the necessity for recognizing that the carcinomatous layer is carcinoma in an early stage. With our knowledge today of the appearance of an early stage carcinoma such a catastrophe could not occur (Fig. 9).

After we had succeeded in determining to our satisfaction what the appearance of earliest stages of carcinoma were like the question naturally arose as to how the earliest stages could be recognized clinically. By most careful comparison of the appearance of the macroscopic operative specimens with the appearance through the speculum it was found that to the naked eye these smallest carcinomata resembled small, white opaque, dull sometimes also slightly wrinkled, spots in the smooth white transparent epithelium of the cervix. That is exactly what has been described years ago by the French and English authors as "leucoplakia" and to which in more recent years Franqu^e and his pupil Hinselmann were the first to draw our attention. By comparing histologically numerous specimens of leucoplakia I was able to state that the great majority were carcinomatous layers but that there were instances in which while the patches appeared in the speculum examination as typical

Fig. 14. Case No. 27318. Hyperkeratotic leucoplakia in leukemia.

leucoplakia yet histologically they were only areas of hyperkeratosis. Such hyperkeratotic areas may originate either in the presence of prolapse when the epithelium is exposed to the drying influence of the air or in the presence of secondary syphilis. With the naked eye it is not possible to differentiate between carcinomatous leucoplakia and hyperkeratotic leucoplakia. With Hinselmann's colposcope by which the field can be strongly magnified and with which it is possible to examine the cervix precisely several interesting morphological details regarding leucoplakias may be discovered but the instrument does not make it possible to distinguish with certainty between carcinomatous leucoplakia and hyperkeratotic leucoplakia. This differentiation can be made only by histological examination.

The clinical diagnosis of leucoplakia is sometimes made difficult because the affected area is so small that it cannot be easily seen with the naked eye. The colposcope however often shows such areas more distinctly but as the colposcopic field of vision is relatively small it is therefore necessary to examine carefully the whole cervix from the external os to the fornix in order to find such leucoplakic areas. An examination of this kind requires skill and time. In a crowded out patient department it is hardly possible to examine a cervix for such minute detail and it is no doubt true that often cervixes which appear to the naked eye as healthy, smooth and un-suspicious, really harbor small incipient carcinomata.

Some method had to be found to locate the suspicious spots more easily and quickly. I discovered this method: vital staining with Lugol's solution. A startling revelation was made—the fact mentioned that normal epithelium of the

cervix contains in its superficial layers glycogen yet no carcinomatous epithellum. This glycogen may be stained on the slide with Best's carmine and on the living patient with iodine potassium iodide solution. When the normal cervix is painted with ordinary Lugol's solution (iodine 1, potassium iodide 2, water 300) the epithellum acquires in about half to one minute a mahogany brown color. However in the areas in which some pathological process is present no brown staining takes place and the epithellum remains white and unstained. Thus diseased spots in the epithellum which escape the naked eye altogether and which can be found only by systematic and painstaking examination of the cervix with the colposcope are made visible in about a minute's time (Fig. 10). The technique used in painting the cervix is as follows: A cervical speculum is placed in the vagina and out of a small cup with a long spout about 10 to 15 cubic centimeters of Lugol's solution is poured and spread with a tampon over the cervix and left in the vagina for about a minute. The iodine solution is then sucked off with a tampon, the cervix and vagina are cleaned of the excess liquid and gently wiped. It is very necessary that the solution should moisten the entire cervix and that no fold should prevent the entrance of the liquid as that might cause wrong diagnoses. If the epithellum shows an unstained spot we must be suspicious of cancer and the tissue here must be examined histologically. As a rule the presence of white, unstained epithelial spots which are free from glycogen may indicate four possibilities:

1. The presence of carcinomatous layers or incipient carcinomata (Fig. 11)
2. The presence of hyperkeratosis a result of prolapse or descensus vaginae (Fig. 12)

3 The presence of hyperkeratosis, a consequence of luetic infection (Fig. 13)

4. The desquamation of the upper layers of glycogenous epithelium which may have been caused by the touching of the cervix with sharp instruments or by the rough insertion of the speculum. Such traumatic desquamations are easily to be diagnosed by their form as they resemble narrow sharp and straight line scratches.

The decision as to the group in the terminology mentioned in which the unstained spots of the epithelium belong can be made with certainty only by microscopical examination. Colposcopic examination alone does not give sufficient evidence in all cases. To obtain material for the histological examination we do not use the V shaped exploratory excision because the changes concern only the superficial epithelium and there is no need to make an excision into the deeper tissues. It is sufficient to scrape off a small piece of epithelium with a small spoon often we may loosen the epithelium with the spoon and with a tissue forceps pull off a thin film. The advantage of this method is that it is necessary neither to proceed surgically nor to suture the wound made by excision. In our experience skillfully removed pieces of epithelium are completely replaced by nature in 2 or 3 days and evidence of removal cannot be found.

Painting with iodine is of value in locating the newgrowth as long as it is in the stage of a carcinomatous layer. As soon as the growth ulcerates, the surface nearly always being necrotic stains brown with iodine and the method is therefore not helpful. On the other hand, ulcerated carcinomata are generally larger and more extensive and are therefore easily visible. In addition they are surrounded eventually by a line of demarcation of carcinomatous epithelium—a white superficial stripe around the ulceration. When a scraping is removed for diagnosis the white stripe should be scratched off and not the ulcerated part or the normal brown epithelium. The simple erosion is covered on the surface with inflamed connective tissue but later, during the first stage of healing is covered with cylindrical epithelium. In both instances the erosion to the naked eye has a more or less dark red, dull velvety color. It becomes only slightly stained with iodine solution. It cannot be mistaken for the white superficial carcinomatous layers. The tissue for diagnosis as already mentioned, should be taken from the white layers but never from within the dark red, eroded or ulcerated parts.

A few months ago we found hyperkeratosis leucoplakia in a case of leukorrhea, which is a very rare incidence of coincidence (Fig. 14).

In our clinic we use the same method to determine the extent of farther advanced carcinomata. It has been found that advanced carcinomata are surrounded by carcinomatous layers, the width of a finger which are totally invisible to the naked eye. If when removing the carcinoma within the carcinomatous layer the operator fails to remove completely the carcinomatous layer itself a recurrence is inevitable. I examined the postoperative specimens of a series of carcinomata apparently radically operated upon but which in spite of radical extirpation had reappeared. It was apparent that these carcinomata were surrounded by carcinomatous layers the greatest part of which had not been removed. This mistake can be avoided if the region of the carcinoma is painted with Lugol's solution before the operation and if the operator observes strictly the limits of stained tissue, so that he removes all growth within the brown zone but by no means within the white carcinomatous area.

A further advantage of this method is that it is easy and does not require expensive instruments. In fact, no special instruments are needed and no special ability or technical training is required. It is not troublesome for the doctor or painful for the patient. Furthermore Lugol's solution is not expensive and the examination takes only 2 to 3 minutes—specular examination is prolonged by 2 or 3 minutes. It makes possible the diagnosis of a carcinoma of the cervix in its very first stage—a factor of much importance in securing absolute healing.

The histological diagnosis is made from the characteristic polymorphic and atypical cells of the epithelium. Up to the present time we have not known of a characteristic of carcinoma which would enable us unmistakably to diagnose it. We cannot be more exact in our definition of polymorphic and atypical tissue the ability to recognize it is merely a matter of training and experience as are many other things in medicine. In medicine many diagnoses are made which cannot be supported by measurements, figures, or by an objective criterion as the evidence of parasites. The internist diagnoses pneumonia because he finds dullness on percussion of the chest but he does not attempt to measure or try to represent the pneumonia in an objective form. He is able to diagnose it because of his medical experience and knowledge. Just as the experienced internist diagnoses pneumonia so we are able through experience and study to diagnose a carcinoma. Anyone who has seen a large number of cases of early carcinoma will have no difficulty in diagnosing the condition. Experience in a number of

cases is the important factor in gaining knowledge—after the diagnosis has been made in 10 cases less difficulty will be experienced with the eleventh and succeeding cases.

I consider the knowledge gained from accumulated clinical experience of great importance. We have kept on file in our clinic each histological specimen, whether positive or negative and have kept in touch with each patient. As a result we have in our histological museum many hundreds of slides on which the diagnoses are insured and have been proved by clinical after-examinations and controls.

When an incipient carcinoma of the cervix is revealed by our method of painting with iodine we proceed at once to operate. In our clinic radiation is not used as a routine treatment in operable cases. If the patient is an elderly woman near or past the climacteric we prefer to do a panhysterectomy rather than to use any other method. Only in young women who have tiny incipient carcinomata do we eventually use the method of amputation of the cervix and we try to remove as much as possible of the cervical canal. The amputated cervix is cut in serial sections which are carefully examined to define the extension of the carcinomatous layer. If the examination shows that the removal was done at one place inside the carcinomatous layer i. e. that the carcinoma was not completely and radically removed, then we proceed to extirpate the uterus and remove at the same time a part of the vagina. We do not consider it wise to do a mere excision of the carcinoma for the following reason. Incipient carcinomata frequently extend high up into the cervical canal—even when the superficial examination shows outside the external os only a small carcinomatous area of a few millimeters in length and breadth. The histological examination may reveal deeper high up in the cervical canal a continuation of the typical carcinomatous epithelium. Mere excision therefore does not remove these parts and the reappearance of the tumor would most certainly follow.

Of course we cannot expect from a method more than it is worth. All circumstances considered some methods have been criticized because of failures when in reality the method was not applicable and good results could not be expected from its use. Iodine painting is a diagnostic method only in the sense that it draws attention to the pathological area. It does not, however, indicate the nature of the pathological process. The pathological diagnosis can be made only upon histological examination. It is true that the experienced surgeon will frequently be able to

distinguish from the shape and the borderline of the white spots whether it is a case of carcinoma or only of hyperkeratosis. Painting with iodine proves only that the epithelium of the cervix is normal everywhere where it takes on the brown color. It does not prove that below the epithelium no carcinoma may be present. A carcinoma which begins in the cervical canal infiltrates the connective tissue and undermines the epithelium without reaching the surface cannot be diagnosed with the method of painting with iodine. As a general rule the deep seated carcinoma is extraordinarily rare, according to our experience the majority of cancers begin at the external os or outside close to the external os. It is true also that carcinomata which fill up the cervical canal and infiltrate the cervix completely almost always have small superficial proliferations which cover the surface outside the external os and when these are painted with iodine the presence of carcinoma is revealed. A very interesting case of this sort has been described by Preissecker.

A patient, 42 years of age had a hazelnut sized carcinoma of the cervical canal. The carcinoma extruded in a tongue shaped proliferation of hardly 2 millimeters in length from the external os. The remaining part of the carcinomatous tissue was hidden in the cervical canal and in the wall of the cervix. Through the small proliferation the carcinoma was discovered with the help of iodine painting and colposcopic examination and the patient was urged to have an operation.

In case there is suspicion that a patient has carcinoma and the iodine painting test has proved to be negative the carcinoma must be searched for in the subjacent parts of tissue by curettage of the cervical canal or by an excision of cervical mucous membrane of the external os. It would be altogether wrong to dismiss the patient without thorough examination. The diagnosis is made easier if the distinct demarcation is visible in the scraping as will be found occasionally. It is recommended that the scraped off epithelium be submitted to glycogen staining according to the Best method. The presence of large, typical vesicular, superficial layers of cells with an abundance of glycogen is positive evidence against carcinoma.

Several years ago the examination of the cervix by iodine painting was introduced in our clinic. In the last 2½ years it has been used systematically. During this time 553 scrapings were made of which 140 were positive. Of course, there are among the positive cases a great number of scrapings from advanced carcinomata to verify the diagnosis and to verify the presence of the line of demarcation between the normal and the

carcinomatous layer. Forty-five patients with carcinomata were operated upon after positive diagnoses were made from scrapings. The total number of carcinoma operations during the same period of time was 90, and 19 of these were early carcinomata and operation was done upon the strength of the positive findings from examination of the scrapings. Six incipient carcinomata were found after routine histological examinations of tissue from patients who had been operated upon for other reasons e.g. fibroids and other conditions. Of these 6 cases, not a single one had been examined by the iodine painting method or from the scrapings. For this reason they should not be included among failures of the iodine painting method. Our method is not used in certain cases, for instance in those in which the cervix does not reveal a suspicion of cancer by speculum examination and the patient has been slated for total hysterectomy the next morning. In such cases, if a carcinoma should be found later the necessary treatment of hysterectomy has already been performed.

Errors may creep in but it is a fact that the number of cases in which minute carcinomata are not discovered has become smaller. 4 years ago they were 3 per cent while today they are only 6 in 425 cases of hysterectomy that is 1.41 per cent. In the 19 cases in which an early diagnosis was made and the patients operated upon clinical examinations revealed no suspicion of cancer. It is remarkable that of these 19 women 8 that is 42 per cent, were less than 40 years of age. On the basis of the fact that with early diagnosis and immediate operation in minute, beginning carcinomata we have raised the percentage of complete cures to 90 or 95 per cent. I believe that it will be possible essentially to improve results in general in regard to carcinoma of the cervix. The method of iodine painting is easy and cheap &

doctor could examine 12 to 15 women with ease in an hour's time, or in a forenoon 5 hours, 75 women. It should be considered a matter of course and it should be our duty to examine for incipient carcinoma each patient coming to us for treatment. It is a fact that in early carcinoma there is no subjective symptom which would force a woman to interview her doctor but we have found through our own experience that if patients are forced to see us because of other troubles, such as fibroids, affection of the tubes, discharge etc. It is only through routine and thorough examination that the cancer is incidentally discovered. We still have today patients who interview the practitioner and seek treatment at hospitals because of some gynecological condition and who upon examination are found to be harboring an early carcinoma of the reproductive organs. This condition could be remedied if every woman would have systematically twice or three times a year a routine Lugol's test. It would then be possible to locate a carcinoma of the cervix in its earliest stages and treatment could immediately be instituted that would raise the percentage of complete healing to 95 or 100 per cent, especially with the improvement of postoperative X-ray treatment. Such a routine examination would not involve great expense and would not require especially instructed men.

SKIITAI TRACTION WITH STEINMANN PIN

RESULTS OBTAINED IN FIFTY TWO CASES OF FRACTURE OF BOTH BONES OF THE LEG¹

MERRILL K. LINDSAY, M.D., F.A.C.S., and RAYMOND M. McKLOWN, M.D., NEW HAVEN, CONNECTICUT

FRACTURES of both bones of the leg in its lower two thirds are observed with greater frequency as traffic accidents increase and although the difficulties involved in the treatment of these cases have been met with varying degrees of success, still they remain a problem requiring careful attention to detail in their management. For the past 5 years, Steinmann pin skeletal traction, followed by suitable plaster splints, has been used in this clinic in the treatment of compound and comminuted fractures of the distal portion of both tibia and fibula with very satisfactory results. It is our purpose to report 30 cases so treated with a brief consideration of the method itself and the results obtained.

Dyck states that the Steinmann pin should not be credited to Steinmann, but rather to the hooks that Malgaigne used. Steinmann is believed to have used these prior to his use of a pin, while Heincke later added the blades and handles. Up to the present time there can be no doubt that the pin has been used with reluctance and that still there exists a widespread belief that the procedure is not without considerable danger. Farr for one states that skeletal traction possesses inherent danger and that necrosis and infection are to be guarded against especially. Estes is of the opinion that plating is to be preferred to skeletal traction until such time as additional statistics show skeletal traction to be of more value than he thinks. In support of his contention he quotes from Sherman, Wagner, Auvray and Elinson. Hitzrot says that pin skeletal traction no doubt has its proper place but that he prefers to use open operative reduction in the treatment of fractures of both bones of the leg, while Wilson on the contrary differs from Hitzrot in that he believes skeletal traction in fractures of this type to be preferable to open operation. In addition Wilson recognizes a well established fact that skin traction is usually out of the question due to insufficient skin surface available. Scudder in his paper on the treatment of recent fractures of the long bones by operation, would try in all doubtful cases the non-operative method first and holds that the honest use of skeletal traction will diminish the number of cases in which primary operation is required. From the difference of opinion available and the results seen in cases of

fractures of both bones of the leg not treated with skeletal traction we can agree readily with the statement attributed to Sir Robert Jones that

If I were asked which fracture was the most difficult to reduce in the lower limb I should say fracture of the tibia and fibula in the lower third.

From January 1927 to September 1931 we have treated 52 cases of fracture of both bones of the leg with Steinmann pin skeletal traction of which we have satisfactory records of 39 (Table I).

TABLE I—FIFTY TWO CASES OF FRACTURE OF BOTH BONES OF THE LEG

1 to 39	Reported in detail in this paper, one case (No. 33-34) having fracture of both bones of both legs.
40	Record incomplete union, however apparently satisfactory.
41	Record incomplete union, however apparently satisfactory.
42	Record incomplete union, however apparently satisfactory.
43	Record incomplete union, however apparently satisfactory.
44	Record incomplete case transferred elsewhere and roentgenograms not completed.
45	Record incomplete unable to follow up patient after discharge.
46	Record incomplete unable to follow up patient after discharge.
47	Record incomplete: roentgenograms incomplete.
48	Record incomplete discharged against advice.
49	Record incomplete roentgenograms incomplete.
50	Record incomplete roentgenograms incomplete.
51	Record incomplete, roentgenograms incomplete.
52	Gas gangrene developed at fracture wound and mid thigh amputation carried out.

In no case have we had either perceptible necrosis or osteomyelitis of the calcaneus through which the pin was inserted. While in all of the 39 cases we are reporting in detail at this time we have obtained satisfactory alignment without appreciable shortening. Functional union particularly has been satisfactory throughout. The procedure is not difficult, and with the usual hospital equipment, it is undertaken with ease if a few simple principles are observed. A brief description of our technique is desirable to facilitate a more thorough interpretation of our results.

PROCEDURE

The point of introduction of the Steinmann pin into and through the calcaneus is of fundamental importance. The blood vessels and tendons about

carcinomatous layer. Forty five patients with carcinomata were operated upon after positive diagnoses were made from scrapings. The total number of carcinoma operations during the same period of time was 90, and 19 of these were early carcinomata and operation was done upon the strength of the positive findings from examination of the scrapings. Six incipient carcinomata were found after routine histological examinations of tissue from patients who had been operated upon for other reasons e.g. fibroids and other conditions. Of these 6 cases, not a single one had been examined by the iodine painting method or from the scrapings. For this reason they should not be included among failures of the iodine painting method. Our method is not used in certain cases, for instance, in those in which the cervix does not reveal a suspicion of cancer by speculum examination and the patient has been slated for total hysterectomy the next morning. In such cases if a carcinoma should be found later the necessary treatment of hysterectomy has already been performed.

Errors may creep in but it is a fact that the number of cases in which minute carcinomata are not discovered has become smaller. 4 years ago they were 3 per cent while today they are only 6 in 425 cases of hysterectomy that is 1.41 per cent. In the 19 cases in which an early diagnosis was made and the patients operated upon clinical examinations revealed no suspicion of cancer. It is remarkable that of these 19 women 8 that is 42 per cent, were less than 40 years of age. On the basis of the fact that with early diagnosis and immediate operation in minute beginning carcinomata we have raised the percentage of complete cures to 90 or 95 per cent. I believe that it will be possible essentially to improve results in general in regard to carcinoma of the cervix. The method of iodine painting is easy and cheap a

doctor could examine 12 to 15 women with ease in an hour's time or in a forenoon, 5 hours, 75 women. It should be considered a matter of course and it should be our duty to examine for incipient carcinoma each patient coming to us for treatment. PLATE IX

compound fractures of this type we dismiss with the statement that it introduces an unnecessary foreign body, only complicating an already complex problem. The method we use appears to

meet every requirement in cases of great comminution where internal fixation is unsatisfactory or impossible. It may be applied quickly and safely under local anesthesia when a more prolonged procedure or general anesthesia is contra-indicated.

CONCLUSION

Skeletal traction, in the form of the Steinmann pin, is of considerable value in the treatment of fractures of both bones of the leg as we have found in the 39 cases reported from this clinic. The

method is simple and safe within the limitation of the operator's technique.

RESECTIONS OF THE COMMON AND HEPATIC BILE DUCTS AND AMPULLA OF VATER FOR OBSTRUCTING LESIONS

RESULTS IN THIRTY CASES¹

WALTMAN WALTERS, M.D. F.A.C.S. ROCHESTER, MINNESOTA
Division of Surgery, The Mayo Clinic

I SHALL present here my results in 30 cases following resection of the common and hepatic bile ducts and of the ampulla of Vater for relief of obstructive jaundice due to strictures and tumors.

The operative procedures can be divided into five groups: (1) hepaticoduodenostomy, choledochoduodenostomy, and cholecystoduodenostomy; (2) excision of the stricture or tumor with anastomosis of the ends of the duct; (3) plastic operation for localized stricture consisting of longitudinal incision of the stricture followed by transverse closure after the method of a Heineke-Mikulicz pyloroplasty; (4) transplantation of external biliary fistula, established when a sufficient amount of common or hepatic duct did not remain to enable anastomosis of the duct and the duodenum; and (5) resection of the ampulla of Vater for carcinoma.

Although the indications for these procedures will be considered later in detail, several conclusions have been drawn from a study of these cases and they will be enumerated here rather than at the termination of the paper. Thus any who have had experience in similar cases will be enabled to compare these conclusions with their own and to analyze the arguments in favor of each procedure. These conclusions are:

1. If sufficient normal duct remains above the stricture to enable its accurate anastomosis without tension to an opening made in the duodenum thus obtaining union of mucous membrane to mucous membrane, results will be excellent, pro-

vided the liver is in satisfactory condition. Failure to obtain such a result can be attributed directly to inaccurate anastomosis, to severe infection of the parenchyma of the liver, or to infection in the walls of the biliary tract itself. Infection in either of the structures mentioned may be accompanied by sand like calculi within the biliary passages.

2. If the stricture or tumor is small or is situated directly adjacent to the liver with normal duct both proximal and distal to the stricture or tumor, excision of the lesion with subsequent direct anastomosis of the ends of the duct probably will be a satisfactory procedure, and can be expected to be followed in most cases by good results. Such is not usually the case, however, if the scarred portion is merely incised and allowed to remain even though the lumen of the duct at this point is increased by a plastic procedure of the Heineke-Mikulicz type. This may be explained by the fact that the remaining scar tissue continues to contract.

3. If the amount of duct which remains exterior to the liver is not sufficient to allow of either procedure, an external biliary fistula can be established and later coned out and transplanted into the stomach or duodenum. This may be expected to be followed with good results in some instances and fairly good results in others.

4. The frequency with which small tumors of the ampulla of Vater cause obstructive jaundice should not be forgotten. Since the tumor is usually small and of low degree of malignancy producing symptoms early and metastasizing late, it

¹Read before the Southern Surgical Association, White Sulphur Springs, West Virginia, December 8 to 10, 1931

thereby lends itself readily to transduodenal removal.

HEPATICODUODENOSTOMY CHOLEDOCHODUODENOSTOMY AND CHOLECYSTDUODENOSTOMY

Hepaticoduodenostomy or choledochoduodenostomy has been carried out in 15 cases (Tables I and II and Case 16) and cholecystoduodenostomy (Case 14) because of the greater ease of attachment to the duodenum without tension, in 1 case. Visible jaundice was present in all the value for bilirubin varied from 1.2 to 17.4 milligrams for each 100 cubic centimeters of serum. With two exceptions, all the patients had been operated on for disease of the biliary tract before they came to the clinic, the gall bladder according to the history having been removed or drained. In 2 cases in which operation had been performed at the clinic for stones of the common duct, there was marked infection throughout the biliary tract and especially in the walls of the duct itself evidences of recurring obstruction of the common duct (due to stricture) developed 4 years later in 1 case (Case 1) and 1 year later in the other (Case 5 in Table I). In all 16 cases, the duration of the jaundice varied from 4½ days to 3 years, and the obstruction manifested itself from as short a time as immediately following operation to 5 years after operation (Tables I, II and VI).

Excellent results are known to have followed operation for at least 5 years in 1 case, 4 years in 1 case, 3 years in 2 cases, more than 1 year in 2 cases, and less than 1 year in 2 cases. The index of excellence has been that the patients have regained their health subsequent to operation and have had no further evidence of biliary obstruction whether pain jaundice, or chills and fever.

Two of the patients reported that they were in good health and free of constant jaundice, but that at times they had pain, transient jaundice or fever of short duration (Table II). In one of these cases (Case 11) jaundice had been present 3 months before hepaticoduodenostomy, cirrhosis of the liver graded 3+ was noted at operation, and a very short fringe of hepatic duct remained above the stricture. Further evidence of hepatic injury in this case was lengthening of the coagulation time to 16 minutes. In the other of these 2 cases (Case 12) bile drained externally for 6 months before hepaticoduodenostomy and in the intra-hepatic ducts were found sandy granular stones. In this instance, too, only a fringe of duct remained for anastomosis. Another patient (Case 9) underwent choledochoduodenostomy in 1926 at which time intrabiliary stones were noted, in addition to the stricture. In 1927 a plastic operation was done

at the stoma made at choledochoduodenostomy and again stones were found. In 1930 I explored the anastomosis and the ducts. The anastomosis was in excellent condition, but in both the common and hepatic ducts were small granular stones. This patient continues, at times, to have occasional biliary colic. The value for bilirubin recently was 2 milligrams for each 100 cubic centimeters of serum, and on test of hepatic function retention of phenoltetrachlorophthalain was graded as maximal (grade 4) but on duodenal drainage a normal amount of bile of normal color was obtained. In other words, the condition of the patient, her symptoms, and the obstruction are results of hepatic and intrahepatic infection with formation of stones and are not due to contracture of the hepaticoduodenal anastomosis. In another case (Case 13), in which the value for bilirubin was 7.5 milligrams for each 100 cubic centimeters of serum, at operation stricture of the hepatic and common ducts extended almost to the hilum of the liver and only a fringe of normal duct remained above for anastomosis. After operation the patient was returned to the care of her family physician and it was recommended that the T-tube remain in place for 1 year because of the accuracy of the anastomosis. It was advised further that should evidences of obstruction again occur it would be necessary to establish an external biliary fistula which later could be transplanted into the duodenum. The patient was free from evidence of biliary obstruction for a year when she again began to have intermittent attacks of colic, chills, and fever without jaundice. She has gained in weight, but states that her condition is not satisfactory. One of the most interesting cases of the group from the standpoint of showing the effect of hepatic injury on postoperative progress, is that of a young woman on whom I operated September 30, 1926 (Case 8) at which time she was deeply jaundiced and had been so for 3 months. I performed choledochoduodenostomy and she was well for 6 months subsequent to the operation then she began to have jaundice, chills and fever but no pain. Examination gave evidence of an enlarged liver and some jaundice of the skin but a normal amount of bile was obtained by duodenal drainage. While she was under observation ascites developed which responded to the use of mercurial diuretics. She returned October 3, 1927. She was not jaundiced and there was no ascites, but an enlarged liver was noted July 10, 1931 5 years following operation, she returned to the clinic with severe jaundice and an enlarged, palpable liver. She died from bronchopneumonia July 21, 1931.

TABLE I—HEPATICODUODENOSTOMY

Case	Age and sex	Serum bilirubin	Date of operation	Symptoms	Previous operations	Postoperative progress
1	63 M	17.4	3-13-26	Jaundiced 45 days	Cholecystectomy and choledocholithotomy 1921	Excellent from 1927 to 1931 No tube
2	50 F	3.3	8-1-28	Jaundiced 5 months	Cholecystectomy (elsewhere) 1927	Excellent from 1928 to 1931 No tube
3	63 M	1.8	3-20-30	Intermittent fistula with jaundice and fever since operation	Cholecystectomy (elsewhere) Nov. 1929	Excellent in 1931
4	41 F	2.4	9-27-30	1 remittent colic and jaundice for 9 months	Cholecystectomy (elsewhere) 1927	Good in 1930; excellent in 1931
5	51 M	2.4	6-16-31	1 remittent colic and jaundice 1 month preoperatively	Cholecystectomy and choledocholithotomy 1925; division of stricture at hepatic duct, 1926; cholecystectomy 1927; choledocholithotomy, 1929; hepaticoduodenostomy (Storer) 1931	Excellent, 11-20-31
6	50 F	1.8	10-23-31	Pain in right upper quadrant for years	Cholecystectomy 1920; cholecystectomy 1927; adhesions (elsewhere) 1929	

Had three intrahepatic stones each approximately 1 cm. in diameter

As has been said one of the 16 patients (Case 14) was subjected to hepaticoduodenostomy for it was believed to be the preferable procedure. This patient had had biliary colic chills and fever for 2½ years and had been confined to bed for a year prior to her operation in January, 1926. This patient I presented at the staff meeting of the clinic on two occasions subsequent to her operation as an example of what seemed clinically to be hepatic regeneration (8). In the year subsequent to operation jaundice would occur at infrequent intervals. During the early part of 1928 she had no further jaundice her stools were normal, and she had no pain. In July 1928 however she had slight hematemesis but on March 4, 1929 she was found to be in good condition except that retention of phenoltetrachlorophthalein was graded 2. She continued to be well until the early part of this year (1931) when she died from sudden hemorrhage, apparently the result of rupture of esophageal varices.

EXCISION OF LOCALIZED STRICTURE OR OF TUMOR, WITH DIRECT ANASTOMOSIS

I have used this method in 4 cases (Table III and Case 27 in table VI) in 3 of stricture and in 1 of neurofibroma. T tubes were used in the anastomosis in 3 of the cases and removed from 6 to 8 weeks subsequent to operation in 2. This method has been used when the stricture was localized was small in extent involved the ducts very near to the liver, and the duct was patent and of normal appearance distal to the stricture. Excellent results have been obtained in each of these cases, more than 3 years and 9 months have elapsed since the first patient was operated on (Table III). The fourth patient died 7 days after operation

from acute suppurative cholangitis and hemorrhage (Case 27).

The patient with the neurofibroma (Case 17) has been reported in detail previously (3). Suffice to say however, that after removal of the tumor the ends of the hepatic ducts were anastomosed to the distal end of the common bile duct over two small T tubes one of which was removed in 4 weeks and the other in 8 weeks.

Considering the excellent results obtained in the 3 cases in this group one may well ask why such a method is not preferable to anastomosing the duct and the duodenum. The answer is that it may be preferable when practicable, yet, I have found it applicable in but 4 of the 29 cases due to the large extent of the stricture and further more I have had the impression that over long periods of time there has been a greater tendency to recurrence of the obstruction at the site of such anastomosis than occurs following choledochoduodenostomy. Discussion of this point should be particularly interesting.

INCISION AND PLASTIC ENLARGEMENT OF THE STRICTURED PORTION

I have distinguished between this method and the preceding one, because in the former the fibrotic portion is completely removed whereas in the method now to be described, the fibrotic portion remains, and later may distort or again obstruct the anastomosed portion by continued contracture. This latter method was used in my earliest cases, and although one patient was free from symptoms of obstruction for 3 years, such symptoms then returned. Another patient has had no evidence of biliary obstruction over a period of 1 year, whereas a third patient has

TABLE II.—HEPATICODUODENOSTOMY AND CHOLECYSTODUODENOSTOMY

Case	Age and sex	Years in hospital	Date of operation	Symptoms	Previous operation	Operative findings	Postoperative progress
7	64 F	47	6-30-25	Biliary fistula; slight jaundice	Cholecystectomy (elsewhere), 1915	Stricture at level of liver; inaccurate anastomosis	Left hospital in good condition, died at home six months later; bile color and jaundice.
8	5 F	16	9-30-26	Jaundice and colic, 3 months	Cholecystectomy (elsewhere), 1924	Live hypertrophied and color of pancreas	Jaundice, chills, fever and enlarged liver for 6 months, 1927-27; no relief of attacks; large liver; 1927-27 jaundice, chills, fever and attacks; 7-27 2 dual bronchopneumonia.
9	16 F	6	2-1-26 1-1-26	Constrict jaundice, colic, and fever since childbirth, 7-4-26	Cholecholecystectomy 1925; pleuro and cholecystectomy 1927 and 1928	Intrahepatic stones, 1925; intrahepatic stones, 1927 with biliary stones, 1928. Abdominal normal.	2-1-26 dismissed, T-tube slipped out, followed by severe colic, jaundice, and locking; July 9-26 and Aug. 1927 severe attacks graded 2, lower abdomen graded 4.
10	45 F	61	8-2-27	Jaundice for years postoperative biliary leakage	Cholecystectomy 1913 cholecystectomy (elsewhere), 1913	Stricture of lower third of common duct; cholecholecystectomy	Excellent until 1931 then occasional colic, jaundice, and fever
	61 F	11	2-19-28	Jaundice, 3 months	Cholecystectomy (elsewhere), 1928	Cirrhosis graded 3-4; short hepatic veins; compression time 4 minutes	Excellent in 1928, chills and fever in 1929, chills, fever, jaundice, and colic in 1931
	7 F		7-4-29	Biliary drainage, 6 months postoperative; chronic jaundice and colic, jaundice weight lost	Cholecystectomy (elsewhere) 1928	Circular stricture (cholesterol stones in biliary ducts; fringes of hepatic duct)	T-tube removed Oct. 1929; Nov. 1929 colic and slight jaundice; 9-29 1931 occasional occasional colic.
11	4 F	71	4-7-30	Jaundice and pain, weeks	Cholecystectomy and T-tube in common duct (elsewhere), 1929	Stricture of common duct; stricture to liver; fringed duct; pancreatic hole; T-tube for 1 year	Sept., 1931 pain, chills, and fever as jaundice; condition not satisfactory
12	4 F	28	4-26	Jaundice and colic, 2 1/2 years	Cholecystectomy (elsewhere) 1913	Cholecholecystectomy	Died in 1926; July 1926 slight jaundice; jaundice good until 4-26-26 died of hemorrhage of esophagus.
13	5 F	7	4-26-26	Biliary fistula, 2 months postoperative; jaundice, colic, fever, and jaundice of week's duration for 5 1/2 years; no weight loss	Cholecystectomy (elsewhere), 1925 cholecystectomy (elsewhere) 1925	Common duct stricture to within 8 mm of liver with stone plus 1 hepaticoduodenostomy over catheter	Catheter held in place by silk thread to entrance until 8-26-26; catheter passed through jaundice remission only 8-26-26 Sept., 1926 biliary obstruction, pain, fever, jaundice; black blood days, jaundice 10 days; Oct. 1927 no attacks for 6 months; Aug., 1928 no attacks, good condition, died suddenly Jan., 1929 (hemorrhage?) sick days.

reported continued good results from operation for over a period of 5 years. I have not the faith in this procedure that may be warranted (Table IV).

In this group as in the preceding one, if it is desired to use a piece of tube or catheter to serve temporarily as a splint for healing and a channel for transmission of bile, experience seems to indicate that a T-tube is best. On three occasions I have had to remove tubes which had been left in the common duct. In 1 case this was required following choledocholithotomy performed elsewhere, in each of the 2 other cases a catheter extended from the duct through the ampulla of Vater into the duodenum and jejunum, and in spite of the fact that three-fourths of its length was in the intestine, intestinal peristalsis failed to detach the catheter from the bile ducts and it had remained in place for several years.

GASTRODUODENAL IMPLANTATION OF EXTERNAL BILIARY FISTULAS

When stricture is complete and involves the common and hepatic ducts, establishment of an external biliary fistula, which later can be coned out and transplanted into the duodenum has given very satisfactory results. Last year I reported 5 such cases in which I operated (9) in 3 of which excellent results have been obtained (Tables V and VI). In 1 of these 3 cases 3 years and 9 months have elapsed since the transplantation and in another, 2 years. Both patients are in excellent health (Cases 22 and 23). A transplanted fistula became strictured in a third patient (Case 24) necessitating re-implantation. A fairly good result has followed. If a patient presents himself with an external biliary fistula, having been operated on elsewhere, before transplantation of the fistula is considered, the condi-

TABLE III.—EXCISION OF STRICTURE OR TUMOR AND ANASTOMOSIS OF ENDS OF THE DUCT

Case	Age and sex	Serum bilirubin	Date of operation	Symptoms	Previous operations	Results
16	32 M	3.8	2-7-28	Intermittent jaundice and colic, 5 years	Cholecystectomy (elsewhere) 1914	Excellent.
17	50 F	15.0	12-21-28	Jaundice and itching 5 months	Cholecystectomy (elsewhere) July 1920	Excellent; T-tube remained in for several weeks.
18	43 F	11.5	10-11-29	Biliary fistula, 4 1/2 months post-operative; intermittent jaundice and itching 5 years, chills and fever	Cholecystectomy (elsewhere) 1920; liver enlarged and firm; neurofibroma obstructing common duct removed	Excellent; T-tube remained in for several weeks.

TABLE IV.—PLASTIC OPERATIONS FOR LOCALIZED STRICTURES

Case	Age and sex	Serum bilirubin	Date of operation	Symptoms	Previous operations	Operative findings	Postoperative progress
19	41 F	0.5	8-6-25	Colic 5 months, jaundice	Drainage, gall bladder and stones removed (elsewhere) 1924	Incomplete stricture common duct at cystic duct; gall bladder contracted to small fibrous mass 1.5 cm. in diameter	Dec., 1925 jaundice, slight pain. Sept., 1925 jaundice and pain absent since 10.8, occasionally slight jaundice chills, and fever 10-7-30 good.
20	30 F	0.0	7-30-25	Colic and jaundice years	Cholecystectomy (elsewhere) 1919	Stricture 2 cm.; re-contracted over catheter; excision duodenal ulcer	Jaundice recurred, 1928 excellent last 3 months, 1929 catheter removed at jejunotomy 1930; intermittent chills and fever 2-5-31
21	38 F	1.4	4-6-29	Biliary colic, 6 weeks; questionable jaundice	Gall-bladder operation (elsewhere) Nov. 1916	Incomplete stricture at junction of common and cystic ducts	T-tube removed 7-8; 1931 condition good; 8-12-30 operation successful.

tion of the common and hepatic bile ducts, and of the gall bladder should it remain must be ascertained. For example, if material resembling white of egg is excreted the probabilities are that the gall bladder remains and that there is a stone in the cystic duct. When bile is excreted the probabilities are that the obstruction is in the common bile duct and that it is caused by stone, by stricture, or by tumor in the head of the pancreas. If transplantation of an external biliary fistula is deemed the procedure of choice it must adequately drain the intrahepatic ducts, and these ducts must be free of stones, otherwise the obstruction will recur. Furthermore the possibility of a more certainly curative type of operative procedure, namely, hepaticoduodenostomy should be considered if sufficient normal duct remains above the stricture or the fistula to enable the duct and the duodenum to be accurately anastomosed.

In May, 1930, I operated on a patient (Case 3) who had undergone cholecystectomy elsewhere in November, 1929, for relief of gall bladder colic, which had been present for 21 years. Subsequent to the cholecystectomy a biliary fistula had developed. When the fistula closed, jaundice and fever would occur and would continue until the fistulous tract again opened and bile was discharged. At operation, the fistula was found to

terminate exterior to a stump of common duct, which was dilated and was 1.5 centimeters in length and 1.5 centimeters in width. The large size of the common duct above the stricture made transplantation of the distal end of the fistula into the duodenum the advisable procedure, this was not done however until three stones, the largest 1 centimeter in width had been removed from the intrahepatic ducts. Had the stones been overlooked they might not have been discharged spontaneously through the anastomosis and symptoms of obstruction might have recurred, thus discrediting the type of anastomosis used. The patient has been in excellent health and without any further evidences of biliary obstruction since his operation.

RESECTIONS OF THE AMPULLA OF VATER

The cardinal symptoms of lesions of the ampulla of Vater are icterus, distention of the gall bladder and chronic obstruction. Mueller called attention to the fact that probably the most common region of origin of the ampullary growth is the duodenal mucosa at the papilla, where an ulcer may develop, and that jaundice, the main symptom, is present except in a few cases in which ulceration of the lesion permits a channel to form through it for the passage of the bile. Such a lesion

THE SURGICAL ASPECTS OF SUPRARENAL ABNORMALITIES

AMONG the interesting advances in surgery have been the identification and surgical removal of tumors of the parathyroid bodies and of adenomata of the pancreas. The effect of both these growths is to increase the activity of the structures in which they are situated: tumors of the parathyroid bodies increase the excretion of calcium derived from the skeletal reserves and those of the pancreas cause overproduction of insulin with hypoglycemia. Identification and removal of such tumors have restored to normal the metabolic activities of the structure in which the tumors were situated.

Further studies on abnormalities of the other ductless glands would indicate that tumors developing in them give rise to characteristic symptoms. Structurally the suprarenal glands are composed of two distinct parts, the cortex taking its derivative from the mesoderm of the Wolffian body and the medulla from the sympathetic nervous system. Tumors arising from the medullary substance are neuroblastomata, ganglioneuro-

mata, and paragangliomata. Neuroblastoma metastasizes early to the liver and lungs in the adult, and to the skull and long bones in children. The ganglioneuroma, benign in type produces no characteristic clinical symptoms. It is usually found unexpectedly at necropsy. Most important tumors of the medullary portion of the suprarenal gland are paragangliomata, benign in character characterized clinically by attacks of paroxysmal hypertension. Excellent results over periods of more than six years have resulted following removal of suprarenal paragangliomata by Mayo Shibley and Porter.

The most frequently occurring suprarenal tumor is that involving the cortex. Several excellent summaries of reported cases have appeared in the literature. To the signs and symptoms thought to be pathognomonic of such tumors Gallais has applied the name *Le syndrome g nito-surr nal* and Krabb  that of "adrenal hirsutism. Briefly the syndrome is accompanied by heterosexual changes, such as virilism, hirsutism, amenorrhea, and occasionally hyperglycemia with glycosuria. After removal of this type of suprarenal tumor the secondary sexual characteristics have reverted essentially to normal as reported by Colletts and Gordon Holmes.

Clinically and experimentally Marine and Jaff  have shown that an intimate relationship exists between the suprarenal body and the other ductless glands. Further support to their thesis is the fact that in the past year Cushing has collected a group of fourteen cases, the clinical picture of which has been similar to that in cases of tumor of the suprarenal cortex, and in many of these cases he

has found basophilic adenomata of the pituitary gland to be present, sometimes the tumors were so small that it was necessary to study the pituitary body in serial section in order to demonstrate their presence. Inasmuch as in most such cases examination of the suprarenal gland gives no evidence of tumor, but in the occasional case there is hypertrophy of the cortical portion of the structure it becomes necessary to approach the problem from the other angle, namely, to determine whether or not patients with syndromes suggesting tumors of the suprarenal cortex may not also have adenomata of the pituitary body. It might seem that this adds to the complexity of making a differential diagnosis between the two lesions. Such, however, should not be the case, since in many instances the suprarenal tumor can easily be palpated through the abdominal wall, or gives evidence of its presence by displacement of the kidney, furthermore in doubtful cases, extraperitoneal exploration of the suprarenal gland can be carried out with ease and comparative safety. Transperitoneal abdominal exploration of the suprarenal glands enables one at the same time to determine the condition of the liver as well as of the ovaries, and particular importance should be attached to the ovaries because of the fact that a particular type of ovarian tumor, called arrhenoblastoma, may be accompanied by symptoms of virilism and hirsutism as reported by Robert Meyer of Germany, and Krock, Taylor, and Wolferman in this country. That such a syndrome is also associated with arrhenoblastoma of the ovary may be explainable by the fact that embryologically, the ovary takes its origin from the wolffian ridge in common with the suprarenal cortex and testes.

As previously stated, since removal of a cortical tumor of the suprarenal alone has

been followed by reversion to normal of secondary sexual characteristics, it would be of great interest to note whether or not the removal of the arrhenoblastomata of the ovary and roentgen treatment of basophilic pituitary adenomata would be followed by similar results.

Even a brief discussion of *Le syndrome génito-surrénal* as characteristic of tumors of the suprarenal cortex would be incomplete without emphasizing the fact that large tumors of the suprarenal gland may occur without this syndrome being present. This is particularly well illustrated in the case of a young woman, aged 32 years, from whom a hypernephroma of the right suprarenal gland, 12.5 by 10 centimeters in diameter, was removed. Although she had had amenorrhoea for eighteen months and had had recurring weekly attacks of pain in the right upper abdominal quadrant, with chills and fever, virilism, hirsutism, or paroxysmal hypertension was not present. Three months following the removal of the hypernephroma, the patient had gained twenty pounds in weight, had had two normal menstrual periods, and had been completely relieved of the attacks of abdominal pain and fever.

The statement of Rowntree and Ball concerning suprarenal tumors is worthy of quotation. "The complexity of the whole problem is especially striking. In many cases, clinical and pathological data indicate involvement of some particular portion of the suprarenal gland and the diagnosis is definite and clear cut. In other instances, complexity of the clinical picture would seem to point to involvement of both medulla and cortex."

This statement, I believe, would apply equally well to cases in which tumors of any of the ductless glands has resulted in *Le syndrome génito-surrénal*.

WALTMAN WALTERS

THE OCCLUSION OF LARGE BRONCHI

THE delay of the development of thoracic surgery was probably due more to the fears and dangers of open pneumothorax than to any other one factor. Satisfactory methods for maintaining adequate respiration in the presence of large openings into the chest have obviated to a large extent this difficulty. Probably the second most important factor that served as a deterrent to the development of thoracic surgery has been the absence of a method by which large bronchi may be occluded with safety. The problem is not a new one as Hippocrates is quoted as giving up in despair in his attempts at causing permanent bronchial fistulae to heal and advising letting nature take its course."

Many different kinds of procedures have been tried on animals in an attempt to find a satisfactory method of occluding large bronchi. It has been the experience of most investigators that it is not difficult to maintain closure of a bronchus following a lobectomy but that the bronchial stump usually reopens following a pneumectomy. Bettmann believes that the successful closure of a large bronchus depends upon its being covered by peribronchial tissue and that pneumectomy can not be performed safely because of the absence of enough tissue to cover the stump. Heuer alone has had a low mortality rate in performing pneumectomies in dogs. Most of the methods which he tried gave good results. These results in which an entire lung was removed were very encouraging but it is to be remembered that the conditions differed from that encountered in the human in that infection was not present and also in that the extremely movable mediastinum of the dog allows shifting of the remaining intrathoracic organs.

The most encouraging results by a method which has probably the largest field of therapeutic application are those that have been obtained recently by Adams and his associates of the Department of Surgery of the University of Chicago. Their experiments were performed on dogs. Adams and Livingstone found that complete stenosis of a bronchus 0.5 inches in diameter was a routine occurrence within 2 weeks following the application of a 35 per cent solution of silver nitrate. A small pledget of cotton attached to a wire rod was saturated with the silver nitrate solution and it was introduced into a bronchus through a bronchoscope where it was allowed to remain for about 10 seconds. Stenosis of the lumen of the bronchus was accomplished by a collapse of its wall and by the filling in of the lumen by the injured elements of the wall and granulations. Subsequently fibrous tissue formation took place. If necrosis of the entire bronchial wall were produced, only the epithelium regenerated. Massive atelectasis was associated with the complete stenosis of the main bronchus of a lobe. The use of 50 and 75 per cent solutions of silver nitrate were sometimes followed by death due to pulmonary hemorrhage.

Adams and his associates have used this method in treating pathological conditions that were produced experimentally. Persistent bronchial fistulae were produced in dogs by a method which they describe. Prompt closure of the fistula took place in all experiments in from 8 to 14 days following the application of the silver nitrate.

Adams obtained little success in his attempts to close bronchi draining pyogenic lung abscesses in dogs. The abscesses were produced by the Holman-Cutler technique in 8 dogs. Efforts were made to occlude the bronchus of the affected lobe in four of these. Complete stenosis of the bronchi was obtained

in 2 dogs after cauterization had been performed four and six times, respectively. This occurred 3 and 4 months after embolization, by which time the abscesses had healed with cessation of drainage through the bronchi. He concludes that pyogenic abscess cavities healed more slowly when stenosis was attempted than when it was not attempted. On the contrary, when abscesses were produced by emboli containing human tubercle bacilli, it was found that healing usually took place more rapidly in the animals in which the bronchus of the diseased lobe was cauterized.

Probably the most significant results were obtained by Adams and Vorwald in additional experiments in which widespread pulmonary tuberculosis was produced in dogs by the introduction of human tubercle bacilli into the blood stream. A saline suspension of human tubercle bacilli was injected into the femoral vein. Two to 6 weeks later massive atelectasis of two of the lobes of the lungs of each dog was produced. The animals which had not died by the end of 4 months were sacrificed. Few or no tubercles were found in the atelectatic lobes, whereas the inflated lobes were studded with millary tubercles. Microscopic examination revealed an occasional small tubercle in the collapsed tissue, while in the inflated lung were many large tubercles with caseating centers. In other experiments, tubercle bacilli were injected into the left

pulmonary artery. The left primary bronchus received an application of silver nitrate 2 to 6 weeks later. At autopsy, varying amounts of tuberculosis were found in the inflated right lung while the atelectatic left lung showed no gross involvement.

As to whether or not the brilliant results that were obtained by Adams and his associates in their experimental work can be duplicated in patients, it is too early to state. The method probably will not be effective in pyogenic infections unless there is an associated fistula to the exterior which allows adequate drainage. One would not, I think, expect to be able to close by silver nitrate a bronchus communicating with a large tuberculous cavity that was associated with a productive cough. Even though such a bronchus could be closed, it might prove unwise to do so. It would seem that one should be able to close by this method the bronchus to a lobe in which the non-productive type of tuberculous lesion is present. As a preliminary to lobectomy for tumors, it should lower greatly the mortality rate if satisfactory occlusion of the bronchus can be produced. The very least that can be said for this simple method that may be far reaching in its therapeutic application is that it supplies an additional means by which many problems connected with the surgery and physiology of the lungs may be attacked experimentally.

ALFRED BLALOCK.

MASTER SURGEONS OF AMERICA

LEVI COOPER LANE

SURGEON founder of Cooper Medical College, now the Medical Department of Stanford University builder of the college buildings and Lane hospital founder of the Lane Popular Lectures (1881) the Lane Medical Lectures (1896) and the Lane Medical Library—this was Levi Cooper Lane.

Dr Lane was a man of strong character activated by a single purpose, namely to advance to the limit of his capacity the cause of scientific medicine To this end he devoted his life with a persistence which, against the handicap of delicate health, knew no check but rose above any discouragement.

Of pure English (Quaker) stock the oldest of nine children of Ira Lane and Hannah Cooper Levi Cooper Lane was born on a farm at West Elkton near Somerville, Ohio May 9 1818¹ His paternal grandparents came from North Carolina and his maternal from South Carolina, crossing the Cumberland Gap in 1807 He had some preliminary education at Farmers College, took his academic course at the Union Theological Seminary Schenectady New York which institution later granted him the degree of Master of Arts and in 1837 that of Doctor of Laws In 1851 he was graduated from Jefferson Medical College, Philadelphia.

He spent the following four years as interne and house officer at Ward's Island New York, and in 1855 passed examination for entrance into the Medical Corps of the United States Navy receiving the highest mark of a class of one hundred a mark which remained the highest in navy examinations for nearly fifty years In the great Naval Hospital at Quarantine Staten Island New York (3000 beds) he learned to know typhoid fever He knew it only too well, for he contracted the disease and was desperately ill He used to say 'These young men have to use a thermometer to make the diagnosis of typhoid fever They do not know typhoid His sea duty was on the U.S.S Decatur and while his ship was in European waters he spent two months in study in Goettingen on furlough He spent two years on the coast of Central America where he learned Spanish and in 1858 at Chinandagua, Guatemala, he performed his first operation for gonorrhea It is of some interest to note that his vessel was the refuge of some of Pinbuster Walker's men

Due to discrepancies in family records the date of Dr Lane's birth has been variously given as 1816 and 1820, but the former is the date undertaken by Dr Lane himself and recorded by him.

LEVI COOPER LANE
1828-1902

Dr Lane resigned from the navy in 1859, and at the invitation of his uncle, Elias Samuel Cooper who founded the first medical college on the Pacific coast (1858), joined him in the practice of surgery in San Francisco and entered the faculty of the medical school as professor of physiology

After Cooper's death in 1862 the school languished, and when in 1864 Dr Hugh H Toland founded the Toland Medical College (now the medical department of the University of California), erecting a commodious building, Lane with several other members of the old faculty became teachers in that institution. In 1870 Dr Lane resigned from Toland College and reorganized the old school

Two years (1874-1876) Dr Lane spent in Europe in intensive study. He attended a course in pathology by Virchow and in London received the degree of 'M R C S'

In 1881 Dr Lane without so much as consulting his faculty, built a great college building and invited the faculty of the medical college of the Pacific, as the old school was called, to join him in developing a new school to be known as Cooper Medical College in honor of his uncle.

It is interesting to note that the gift of the building was on condition that there be given by the faculty each winter a course of popular medical lectures. This course of lectures has been given annually ever since, the fiftieth course being completed this year. In this matter of the instruction of the general public in medical science Dr Lane was at least thirty years ahead of his time.

In 1890 Dr Lane built an addition to the College building, doubling its size and in 1894 built Lane Hospital (250 beds). He was proud to state that he had built these buildings 'with moneys earned by himself in his profession'

Among the most far reaching of Dr Lane's accomplishments was the founding of the Lane Medical Lectures, for students and practitioners. The happy choice of William Macewen, regius professor of surgery, University of Glasgow, to inaugurate the course, gave the lectures such prestige that there has never been any difficulty in securing as lecturers men of the highest attainment in medicine, surgery, and medical research, such as Sir Michael Foster, Sir Thomas Clifford Allbutt, William H Welch and Sir Patrick Manson.

Dr Lane died February 18, 1902. By the will of his widow, whose death occurred the following August, one-third of his estate was given to Cooper Medical College, all that could be given by the then law of the State of California, for the purposes of a medical library. This library, since known as the Lane Medical Library, is the largest and most complete west of Chicago, and ranks perhaps fifth in importance in the United States. It is not merely a College library, but is administered for the benefit of the medical profession.

Though never robust physically, Dr Lane, by virtue of self discipline and perseverance, conducted an enormous medical and surgical practice. All his life he was a student. He early learned to divide his sleep, working at his books the

larger part of every night. Six nights in the week he read medicine, the seventh general literature. He read easily Greek Latin French, German Italian, and Spanish. As an exercise in Greek he religiously read Hippocrates once a year.

He wrote comparatively little, his thesis on "External Urethrotomy" and one or two other papers were in Latin, in addition these were a few medical papers e.g., on supracondyloid fracture of the elbow read before the American Surgical Association 1895 a few pamphlets, mostly controversial, for he lived in a period when personalities were prominent. In the matter of the supracondyloid fracture of the elbow he insisted upon the 'straight position, molding the joint daily by passive flexion. He secured excellent results, doubtless more because of the molding of the soft callus than the position of retention. But he was wont to classify surgeons as good or not according to whether they treated fracture of the elbow in the straight position or otherwise.

He translated Billroth's *Surgical Pathology* for his students laboriously writing out the translation in blank books and finishing this or that chapter as seen by his notes, at three or four in the morning. He projected a great textbook on surgery in three volumes, but lived only to complete the first, *Surgery of the Head and Neck* which, though perhaps ill timed nevertheless is a mine of personal observation rich in reference to the surgery of the nineteenth century.

A skillful anatomist he maintained for many years a small private dissecting room where he was wont to prepare himself for any unusual operation by dissecting the part ahead of time.

He was a humanitarian of intense feeling for the unfortunate, and while not interested in the conventional organized charities, did much private charitable work, and no one knows how much. He said 'It is a great thing to relieve pain. A keen observer of human character he had no patience with a shirk or a malingerer and his incisive tongue and classical vocabulary left no misunderstanding as to the duty of the individual to society but on the other hand he often said he wished no man to feel too poor to have his services. I heard him say that any man who had been in Andersonville or Libby prison could have his services without charge.

If one were to seek a single word to indicate the dominant feature of his character it would be loyalty for his friend could do no wrong and his enemy no right. How penetrating the glance of his keen blue eyes as he sought loyalty in others!

As a surgeon his methods were not brilliant but simple and direct. He was not greatly original and yet at the instance of a mother whose child was afflicted with microcephalus, who asked him could he not unlock her baby's brain and give it a chance to expand, he performed a craniotomy similar to that done by Lannelongue many years later. Vaginal hysterectomy he worked out as an original anatomical problem before 1880 not being aware that the operation had been

done in France in the early years of the nineteenth century and had been forgotten. He was a pioneer in suprapubic prostatectomy and devised a long pair of scissors with suitable curve for cutting away the middle and lateral lobes of the gland, guided by a finger in the bladder. He did much work on goiter and was very successful. His method in pre-antiseptic days was to shell out encapsulated odenomata and in diffuse goiter to transfix the gland with a peculiarly shaped transfixing forceps of his own design, cutting the tissue between ligatures, therefore, with little bleeding. He called thyroidectomy the operation of a hundred ligatures. He used silk for ligatures and left the ends hanging out of the wound for drainage to be drawn out as they became loosened. He performed many notable operations, having the courage to attack the most desperate cases. On one occasion, while operating for extensive cancer of the mouth, he was obliged to ligate the common carotid and in a few hours ligated the other, practically simultaneous ligation of both common carotids. The man lived for a number of years, a monument perhaps more to the size of his vertebral arteries than to the prowess of his surgeon. He ligated the abdominal aorta for aneurysm but never published the case. The man lived four or five days, when, pulling himself up into a sitting position, he strained and tore open the artery.

Towards the end of his career he was afflicted with a slowly progressive disease, purulent bronchitis, and some said he suffered from diabetes. He was engaged in writing the second volume of his textbook on surgery, *Surgery of the Chest and Abdomen*, struggling to complete it. At first he wrote twenty pages in a night, then fifteen and then ten, and as his weakness progressed the pages gradually diminished to three but he wrote these three, then two and finally one day before he was obliged to give up.

He had no children, but Cooper Medical College was to him a child. Feeling that the institution had been built up by the devotion and self sacrifice of himself and faculty (surely the young men who succeeded him could carry on with similar devotion), he had inserted into the deeds of the property to the corporation clauses to the effect that should the directors at any time cause the college to be united with any other institution, the property should automatically revert to the state. However, shortly before his death it was gradually borne in upon him that the cost of medical education was increasing by leaps and bounds, that substantial salaries had to be paid to the non practicing members of the faculty, the physiologist, the anatomist, the pathologist, the chemist, and the bacteriologist, and costly laboratories must supplant the lecture room. There was in sight no adequate endowment. Therefore, realizing that the institution could not stand alone and remain a class A medical school, he had the entire property deeded to him by the corporation, whereupon he redeeded it to the college with restrictive clauses omitted. He went further and entered into negotiations with David Starr Jordan, president of Stanford University, looking toward the

sorption of the school in that University. The amalgamation took place in 1909, seven years after Dr. Lane's death. The conditions on which the directors of the college deeded the College property to Stanford University were simply that the property should be used for purposes of medical education in the sense of teaching young men and young women to be practitioners of medicine and that Dr. Lane's memory should be suitably preserved. Since buildings become out of date and have to be replaced, Dr. Lane's real monument is the Lane Medical Library and the Lane course of Medical Lectures—more enduring than brick or stone.

EMMET REXFORD

EARLY AMERICAN MEDICAL SCHOOLS

THE MEDICAL COLLEGE OF VIRGINIA

WYNDHAM B BLANTON M.D., RICHMOND VIRGINIA

THE third medical school to be established in Virginia was organized in Richmond in 1838 as the Medical Department of Hampden Sidney College. It began as a private venture inaugurated by a group of young men several of whom had previously taught in other institutions. It was hoped that the new institution would attract some of the 400 and more students who were every year leaving Virginia for study in Northern medical schools. The founders were an exceptional group of men. Augustus L. Warner (-1847), graduate of the University of Maryland and fresh from the chair of anatomy and surgery in the University of Virginia became dean and professor of surgery and surgical anatomy. He possessed marked ability as an administrator and surgeon and was the moving spirit in the new enterprise. John Cullen (1797-1849), native of Ireland and graduate of the University of Pennsylvania was accorded the chair of the theory and practice of medicine, adorning it until his death in 1849. Lewis Webb Chamberlayne (1798-1854) of proud Virginia ancestry, likewise a graduate of the University of Pennsylvania, held the chair of materia medica and therapeutics. Socrates Mfaupin (1808-1871), 'a quiet little gentleman' and a graduate of the Medical Department of the University of Virginia, assumed the chair of chemistry and pharmacy. In 1853 he resigned to accept a similar position in his alma mater where he was shortly honored by being made chairman of the faculty. Richard Lafon Bohannon (-1887), still another graduate of the University of Pennsylvania, was made professor of obstetrics and the diseases of women and children, a position he acceptably filled until his death in 1887. Thomas Johnson became professor of anatomy and physiology. He had enjoyed the advantages of study in France under Laennec and had recently taught anatomy and surgery in the University of Virginia.

The College opened its doors in the old Union Hotel on East Main Street which had been converted into creditable teaching quarters and an infirmary. There was an impressive anatomical

museum and excellent chemical apparatus. In a short while plans were under way for a much more elaborate building and an entirely new structure on Shockoe Hill was soon ready for occupancy. The Egyptian building as it is still called was erected on land donated by the city with money loaned by the Legislature from its Literary Fund. The catalogue of 1845 announced that 'the magnificent and commodious College Edifice has been completed'. Lecture rooms, dissecting hall, infirmary were all under one roof.

The enrollment steadily grew from 46 in 1838 to 80 in 1851. The attendance did not exceed this number until the Civil War when classes of more than 200 were taught. Ninety per cent of the students were from Virginia. The tickets of each professor were paid for separately, and for many years averaged between 15 and 20 dollars a subject.

The course of instruction was modeled after that of the older Northern schools. It consisted of two sessions of 4 months each, the second a repetition of the first. Graduation was contingent on two terms of study preceded by a year under some reputable physician, or attendance on the summer course, a thesis, an oral examination, and a fee of twenty five dollars. In the catalogues stress was laid upon the advantages the school had to offer Southern students—unlimited material for anatomical dissection, bedside instruction in an infirmary purposely housed under the same roof as the college, and the opportunity to study diseases peculiar to the South in their native habitat. In fact the type of clinical instruction given offering as it did, ready access to ward patients and ample opportunity to follow in each case the progress of disease, was loudly proclaimed as superior to the amphitheater method which was then so popular in Philadelphia.

This tranquil course of events was disturbed in 1854 by an unhappy schism arising out of a disagreement as to who had the right to appoint new members to the faculty, the Board of Hampden Sidney College or the medical faculty itself. The

Fig. 1. Old Union Hotel, Nineteenth and Main Streets, first building occupied by Medical Department of Hampden-Sydney College.

quarrel assumed large proportions and excited a heated pamphlet warfare. It was ultimately settled by the legislature granting the medical faculty a new and separate charter. Thereafter the school was known as the Medical College of Virginia.

The new freedom was dearly bought, because a large element of the profession of Virginia was from this time on allied against the institution. This element controlled the medical journals of the state and until the Civil War violently attacked the faculty, relentlessly exposing every weakness of the college. Dr B. R. Wellford, the professor of materia medica and therapeutics, a man of national reputation and unimpeachable character, bore the brunt of the attacks, choosing as he did to become the mouthpiece of the faculty.

In spite of outside interference the institution made progress and some exceptional men were to be found in her faculty during this period. Jeffries Wyman succeeded Thomas Johnson and gave great and lasting impulse to the teaching of anatomy in the school. Under him the anatomical and pathological museum grew apace. Wyman terminated his teaching in Richmond to become

Hersey professor of anatomy at Harvard. Meredith Clymer who held the chair of medicine from 1848-1849 subsequently occupied several professorships in the North and achieved distinction in the field of nervous and mental disease. More memorable was the brief occupancy of the chair of the Institutes of Medicine by Charles Edward Brown-Sequard. The famous savant taught in the college for a single session. He filled the basement of the college building with experimental animals, let down into his own stomach sponges on strings, withdrew them before the class to demonstrate digestive fluids in action, and did many another novel and startling thing to the delight and wonder of his class. His passionate love of science and the facility he possessed of compelling nature to reveal her secrets for first-hand observation, made a lasting impression on his students.

The Civil War added immensely to the responsibilities of the college. In the fall of 1859 Dr Hunter McGuire was successfully conducting an extramural school in Philadelphia. Through his personal influence and effort the Southern students in both the University of Pennsylvania

Fig. 2. Egyptian Building

and Jefferson were assembled and transferred *en masse* to Richmond. Two hundred and fifty strong they were met at the station by enthusiastic citizens and students and later welcomed by Governor Wise in an address in the Capitol Square. Many of these students elected to continue their course in the Medical College of Virginia. This trebled the student body and taxed the institution to capacity. The Legislature rallied to the support of the college, voting thirty thousand dollars for a new hospital which was shortly erected adjacent to the college. Throughout the period of the war the faculty taught at fever heat, giving two courses a year. It was the only Southern medical school which never closed its doors during the period of hostilities. Thousands of soldiers were cared for by the faculty and students. Several of the faculty, in addition to their teaching positions, held important posts in the military service of the Confederacy. Charles Bell Gibson, professor of surgery, was surgeon in chief for the Virginia forces. James B. McCaw, professor of chemistry and pharmacy, was in charge of the Chimborazo Hospital, an institution that cared for more than 75,000 sick and wounded during the war. The graduation of large medical classes twice a year and the entrance of these graduates into the medical service of the Confederacy was no small part of the contribution of the college to the cause of the South.

The college faced the *post bellum* reconstruction bravely. In spite of poverty and a student body reduced at one time to a bare corporal's guard, efforts were steadily made to improve the standards of teaching and to give the students access to better clinical material. Clinical instruction was offered in Howard's Grove Hospital—an institution of five hundred beds—the college hospital, the Richmond Almshouse, and the City Dispensary.

The faculty after the war was composed of R. T. Coleman in the chair of obstetrics, D. H. Tucker in medicine, J. S. Wellford in therapeutics, J. B. McCaw in chemistry, A. E. Petricolas in anatomy, and Hunter McGuire in surgery. Naturally many changes were wrought as time went on. In 1881 Hunter McGuire resigned and was succeeded by J. S. D. Cullen, of almost equally illustrious war record. Frank D. Cunningham followed Samuel Logan in anatomy in 1867. E. S. Gaillard, editor of *Gaillard's Medical Journal*, taught pathology from 1867-68. Levin S. Joynes and Otis F. Manson were added to the faculty.

The elevation of standards came slowly—too slowly for the critics of the college. The old charge of a "closed corporation," an institution run for personal advantage, began to appear in the journals. The fees were said to have been cut, scholarships abused, and the two short courses

Fig. 3. McGuire Hall, principal teaching unit, Medical College of Virginia.

for graduation were held to be entirely inadequate in preparation for the practice of medicine.¹ *The Journal of the American Medical Association* in two withering editorials, charged that the faculty was opposed to the medical examining board and had sanctioned the appearance of their students before a committee of the legislature asking exemption from the state examination. This was convincing evidence to the *Journal* that the work of the college was not what it should be. The Governor of the state took a hand and appointed an entirely new board of trustees. After months of futile effort to obtain control of the college, the matter was settled in the courts in favor of the old board.

In May 1893, a rival school the University College of Medicine was organized in Richmond. At its head was Hunter McGuire, a former professor of surgery in the old school, whose reputation was now at its height. About him a large faculty was gathered to teach medicine, dentistry and pharmacy as the three departments of the new school. From the first this school attracted a large attendance. The enrollment the second year was 180. A graded course was offered in all departments and in medicine extended over 3 years. The institution first occupied the former residence of Alexander H. Stephens, vice-president of the Confederacy. In a few years it was in

possession of a new building of its own. A disastrous fire in 1910 produced a desperate situation from which the institution was rescued by the munificent contribution of \$100,000 from the citizens of Richmond toward the erection of another new building. The Virginia Hospital with 125 beds, a training school and "a large corps of trained nurses" was close by and under the entire control of the faculty.

The presence of the new school was an admirable stimulus to better medical teaching in Richmond. The old college began at once to look to its laurels. The faculty was enlarged and George Ben Johnston, who at this time became professor of surgery asserting his natural gift of leadership assumed much the same rôle in the old school that Dr. McGuire did in the new. From now on it was a battle between these superior men and their respective faculties. The old school began by reorganizing its hospital which after 1895 was known as the Old Dominion Hospital. A school of nursing was instituted by Miss Sadie Heath Cabaniss, a graduate of Johns Hopkins Hospital under Miss Isabel Hampton. Under her high ideals and strict discipline it became a school to be proud of. The medical curriculum was expanded and lengthened until in 1894 it became a 3 year graded course of instruction and in 1897 in imitation of its rival, it was subdivided into the three departments of medicine, dentistry and pharmacy. In 1899 the 4 year course was adopted. To its surprise the presence of a competitor instead

¹ It is held to say that students on admission were required to have studied under an approved preceptor for 1 year, and that in addition to the two short terms an occasional summer course was offered by the faculty.

of reducing its enrollment increased it so that by 1895 its students numbered 139. The intense rivalry of the two institutions created two bitter factions in the medical profession of Richmond, but it put nearly every physician to studying and teaching medicine and accomplished what the old school alone had not been able to do—it stemmed the tide of Virginia students seeking a medical education in Northern institutions. In a single year Virginia medical students in Virginia institutions increased from 225 to 450.

Such a situation in a city as small as Richmond could not always endure. It became more and more difficult to find money to support both schools, for both had radically reduced tuition—

in the case of the old school to sixty five dollars a year. Leaders wearied of the incessant struggle and longed to exert their united strength in the general cause of medical education. In 1913 old differences were forgotten. The boards of the two institutions met in joint session, amalgamated the two schools and selected a new faculty. Since that time, the Medical College of Virginia, as the consolidated schools were called, has continued to expand and prosper. Now strictly a state institution which is open to both men and women, controlling four hospitals with full time professors in all important departments the college is annually giving instruction to more than eight hundred students.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IN their monograph Sicaud and Forestier present a comprehensive work on the use of Iodidol as a diagnostic medium. The greater part of the work is devoted to the application of Iodidol as a diagnostic medium, relatively little being given as to its action as a therapeutic agent.

The book contains full and comprehensive instructions for the use of Iodidol as an adjunct to radiology in the exploration of various body cavities. Many excellent illustrations depict typical lesions as revealed by this diagnostic aid. The indications for the use of Iodidol in the subarachnoid space in the study of medullary compressions are

considered in detail by the authors and the adverse criticisms of the method are answered at length.

The authors do not claim that Iodidol is an all around substitute for careful clinical examination or for the already known radiological contrast media but they do claim that it reveals many cavities and tracts that were heretofore not possible to photograph by means of the roentgen ray and that it is therefore an invaluable adjunct to clinical examination in many atypical and obscure cases. There is appended a very complete bibliography which is classified according to the chapters of the book, the chapters discussing the different regions treated. Because of this arrangement the book has added value as a handy reference volume in its field.

To the early days of the War I was visiting Sir Robert Jones, of Liverpool when the *Lusitania* arrived from New York with John B. Murphy on board. In the afternoon he came to visit Sir Robert, and there I met him for the first time. Jones the acknowledged master of orthopedic surgery was at work. Many of you know him and place him as we do as a superman who has the secret of perpetual youth. The first operation on the list was for the correction of a malunited Pott's fracture, the second was bone grafting for an ununited fracture of the leg. I can still see Murphy keen and intent watching every movement every detail. The cases he was observing were after his own heart. He had written repeatedly on ununited and malunited fractures in the region of the ankle in the sphere of bone grafting he was at his best. I waited for him to speak. I expected to hear something of the methods he himself had advocated but he only gave expression to his unbounded admiration for the operative dexterity of another man. Here was a generous personality quick to appreciate and quick to acknowledge perfection when he saw it. In plain language Murphy had the instincts of a great gentleman.

From Liverpool we traveled together to Leeds. He was communicative and talked freely. It was an experience which I can never forget. He was familiar with and was interested in the work of my colleagues in Ireland. He invited me as his guest to Chicago, an invitation which alas in War time I was unable to accept.

At Leeds we saw Lord Moynihan perform an intestinal anastomosis. Some pardonable egotism might have been expected from such an onlooker as Murphy possessed as he was of an unrivaled knowledge in this branch of surgery. Once again with all sincerity he played the part of the appreciative admirer. He whispered to me that he would have traveled all the way from America to be a witness to the operation which he had just seen performed.

Murphy's unstinted recognition of the work of others would alone have secured him a high place in the esteem and affection of the profession in every land.

It would not be a true picture, if Murphy was portrayed as a man surrounded by surgical intellectuals worshipping at the shrine of his clinic in Chicago. If this were so he would rank above human mortals. He had his critics, he had his enemies. There were those to whom Edmund Burke alluded (writing when he was 18 years of age) as "men who look with an envious eye on talents they can never hope to equal and are willing to bring everything to their own level." Murphy experienced some of this envy and opposition. It is in the nature of things and it can be understood.

It is perhaps a pardonable conceit to couple Murphy's name with those who are associated with the making of the history of Irish medicine. There is a long line of ancestors but after a cursory glance at the ancients it will be more profitable to pass over the intervening centuries and concentrate attention on Murphy's immediate predecessors and contemporaries.

Looking back to the year 37 A.D. almost two thousand years ago we find that the King of Ulster was wounded in the head by a missile and was attended by the great physician Fingen. "Fingen knew from the fumes which rose from a house how many were ill in the house, and every disease which prevailed in the house. This must be true, for it is recorded in the Book of Leinster. The wounded King was stitched with threads of gold because the colour of his hair was the same as gold." These were the days when Celsus (about 30 A.D.) spoke of sutures ligatures and the dressing of wounds.

Almost eighteen hundred years after Fingen we had in Dublin such figures as Abraham Colles, Dominick Corrigan and R. J. Graves. Abraham Colles goes down to posterity for his accurate description of the fracture which bears his name. It was published in the *Edinburgh Medical and Surgical Journal* in 1814. He had, of course, none of the advantages of radiography, he never saw the fracture during dissection. And yet from clinical observation, in fifteen hundred and twenty-eight words, he gave an original and

accurate description of a complex injury. Subsequent investigation found his observations to be almost faultless. This article, together with the accounts of Colles' law and Colles' fascia will be referred to while literature remains.

When studying medicine in Edinburgh Colles refused to associate with other Irish men on the ground that all people make it a rule to fight and quarrel with their own countrymen rather than with any other. In this respect he did his countrymen an injustice. They are not fastidious in the making of such a choice.

Colles was a man of considerable physical strength and determination. On one occasion he walked from London to Edinburgh a distance of four hundred miles. He earned less than nine pounds the year he started practice in Dublin but like Murphy he sprang for ward and he was elected president of the College of Surgeons in 1802 when he was twenty-eight.

In this same year Sir Dominick Corrigan was born. When thirty years of age Corrigan placed his permanent mark on the history of medicine by his description of 'Inadequacy of the Aortic Valves.' The water hammer pulse and Corrigan's pulse are accepted as synonymous terms. Corrigan had this in common with Murphy—he was the inventor of a button—the two buttons were designed for very different purposes, Corrigan's button was used to fire all and sundry at a time when counterirritation was the order of the day. Sometimes it is used in Dublin even now as an alternative to diathermy and I have seen gratifying results.

The immortal Graves was five years the senior of Corrigan and still more distinguished as a clinical physician in the eyes of those most competent to judge. But as a practitioner Graves did not find the same favor in the public eye. The story is told how when a passenger on board a brig bound from Genoa to Sicily in mountainous seas, he smashed a boat with an axe to prevent the abandonment of the ship by a terrified crew. He repaired the leak in the valves of the foundering ship with leather from his boots and took personal charge of the navigation.

I have purposely mentioned the names of two great physicians and I will mention others, for medicine cannot be divorced from surgery. They and their various handmaids are interdependent without the one the other must totter and fall.

Graves as a manner reminds us of the lines written by an author not free from bias

See one physician like a sculler piles

The patient lingers and by inches dies

But two physicians like a pair of oars

Wast him more swiftly to the Stygian shores

Within my own memory in Dublin there were some outstanding figures in the surgical profession. They have crossed the river and are waiting on the other bank to answer their names to the roll call of the selected few.

Among them was Richard Butcher, William Wheeler (the writer's father) William Stokes, Henry Swaney, Edward Bennett, John Mc Ardle and Edward Taylor.

Butcher was born in 1819, his father was an admiral, one of his brothers was a bishop. His nephews were outstanding politicians in the British House of Commons in recent times. He died in 1891 leaving all his surgical manuscripts and private papers, his library, his instruments and other articles which he prized as a legacy to my father.

Butcher was surgeon to Mercer's Hospital,¹ to which I have been attached for 28 years. I remember him attending me as a child for a broken arm sustained in a struggle with a nurse for the possession of a toy. The records of his surgical work in this hospital occupy many volumes. His manuscript notes in my possession prove the meticulous care with which each surgical problem was approached. They are a record of indefatigable industry and of profound surgical acumen. Later I will mention some of the cases which recently have been dealt with under the same roof.

He was an honorary fellow of the College of Physicians of Philadelphia. He was a man possessed of some vanity and of great muscular strength. Like Samson, his hair was long and hung in carefully tended curls over his neck and shoulders. His biceps, revealed

¹The Dublin Hospital to aid of which Handel first played. The Museum.

to onlookers when he was operating was the admiration of medical students. A plaster cast of an arm, typifying perfection in development is to be seen in the anatomical department of Trinity College. Legend has it that it is the arm of Butcher. In America and in the medical schools of Europe he is best known as the inventor of Butcher's saw.

*Some follow letters, others follow law
And some find happiness in war's alarm
But he upholds the glory of the saw
And wields his weapon with titanic arm*

He kept a book (in my possession) of newspaper cuttings. The complimentary references to himself are diligently underlined.

An Irish newspaper dated December 1874 relates how two of the finest athletes in Washington were members of the medical profession, "One of them says the article 'lifts 1,000 pounds with his hands and puts up a dumb-bell of 130 pounds. The other is said to be the strongest man in Washington for his size. He lifts 400 pounds with one hand and suspends 63 pounds at arm's length on his little finger. Underneath this pasted in paragraph is written in Butcher's handwriting—"I have done the same and greater feats."

In July, 1838 when 19 years of age he was studying in London. He conceived the idea of getting over the roofs of the neighboring houses on to the back of the lion which surmounts Northumberland House Gate in the Strand. With the help of a rope he succeeded. "I have placed the picture of Northumberland House in the book," says Butcher "because I performed a great feat on it."

I have accused Butcher of vanity but if time were of no consequence, I could from voluminous documents show that this human frailty was entirely overshadowed by a disposition of simplicity intermingled with understanding and remarkable professional skill.

In about the year 1871, two policemen were shot in the streets of Dublin. One was attended by Butcher in Mercer's Hospital and recovered. The other, a man called Talbot, was operated upon by Stokes and died. The two results were contrasted in newspaper articles. It was publicly suggested that Talbot

was not killed by the bullet but had succumbed to indifferent surgery. "We defy you my lords and gentlemen of the jury," says one paper "in presence of facts so emphatic, and a contrast so instructive, to declare otherwise than that Talbot did not die of the bullet but of the probe, knife, and forceps." The prisoner in the dock was acquitted.

Apparently there was no control over newspaper comments in those days. The medical student and his friends did not heal matters by the publication of verses of which the following are a couple of lines: "Who killed Talbot?" "I," said Bill Stokes, "with me probes and me pokes. I killed him—all but." Stokes was unfairly treated by the press and by the public in this matter. He was a surgeon of high repute, a fine speaker and by his writings added his share to the knowledge of the day.

Stokes the great Dublin physician, was the father of the surgeon to whom reference has just been made. A life-long friend of Graves, he became famous in Dublin and abroad for his contribution to the value of the stethoscope, and his description of what is known as the Stokes-Adams syndrome, and Cheyne-Stokes respiration. John Cheyne's account of this type of respiration was published in the *Dublin Hospital Reports* 1818. The description was clarified and exemplified by William Stokes in the *Dublin Quarterly Journal* in 1846. Hippocrates described the exact same type of respiration when he was picturing the condition, so often alluded to in modern medicine as the "typhoid state."

Swanzy was an oculist of high international standing. Bennett lectured in surgery in Trinity College, he was probably the greatest authority on the subject of fractures belonging to the old school. Bennett's fracture of the metacarpal bone of the thumb was described in the *Dublin Journal of Medical Science* in 1882, with the same accuracy as Colles described fracture of the radius a generation before. Later, I will mention his discovery in connection with congenital laryngocele.

McArdle (a friend of Murphy's and to whom Murphy alluded when speaking to me of Ireland) has only recently left us. His early writings *inter alia* on the surgery of the stomach

ach stamp him as a man in the front rank of his time.

It seems but yesterday since E. H. Taylor was writing his book on operative surgery and applied anatomy. He died in his prime after serving as president of the College of Surgeons.

Finally came my own father. He was Butcher's favorite pupil. They were close and intimate friends. He was known by medical students as the Butcher's boy. In 1883 (the Centenary year) he became president of the College of Surgeons. He died at the age of 55 in 1897. In 1886 he described a case of dilatation of the pharynx cured by pharyngotomy the first case of its kind on record. I have in my possession the sections of skulls in the region of the temporal bone on which he based an original description of an operation for mastoid and tympanic disease in 1883. The *American Journal of the Medical Sciences* described the paper as admirable. Recent writers have advocated the adoption of the operation which he designed. In an address entitled 'What has Society Gained by the Progress of Modern Surgery?' almost 50 years ago he speaks with familiarity of intussusception, pylorectomy, renal cysts and aneurysm and of surgery generally as a far grander and nobler science than was that of former years. He denounced Listerism as it was practised at this time. He ridiculed the carbolic spray and the special layers and the particular preparation of the gauze but he was an early convert to antiseptic surgery which he claimed was entirely different from Listerism. He said that those who imagined that they could wash the air of germs by means of a spray and keep them from a wound by gauze and protective were living in darkness. Surgical cleanliness, he declared was the keynote of success. He was an advocate of aseptic surgery before the immortal Lister had seen so far. In these matters he saw eye to eye with Lawson Tait.

Like his great master Butcher he was a man of powerful physique. He was champion light weight boxer as a young man when he served in the army. He married a first cousin of George Bernard Shaw.

In 1882 a land agent was shot in Belmullet, an out of the way village in the West of Ireland 40 miles from the nearest railway station.

The Government at Dublin Castle, under the direction of Mr. Burke the chief secretary took responsibility for the shooting of Carter as proper police protection had been neglected. My father was sent to Belmullet on behalf of the Government to give surgical assistance to the wounded man. In these old days of primitive trains and outside jaunting cars, each journey took almost a day and a half to complete. Several visits were paid and a leg was amputated in 16 seconds! Political feeling was running high the surgeon found it necessary to carry a revolver and to be protected by police. He charged his account to the Government at 125 guineas a visit by previous arrangement. The total bill amounted to £1 147 18 0 including 50 guineas for the operation. The Government repudiated liability and there was an action at law. During the evidence Butcher swore as an expert that if he had been employed he would have doubled the fees.

In those days there was not the fraternal feeling which rules now between the surgeons of one city and those of another. There was considerable rivalry between the surgeons of London and of Dublin. When reference was made by Counsel for the Crown to the more moderate charges of first class London surgeons Butcher full of fight, delighted the Irish Jury by suggesting that such men did not exist. The case was withdrawn after a graceful statement by the attorney general and the fees were paid in full.

In mentioning some of those who did credit to the Irish school of medicine, I have not lost sight of Murphy. It was the environment of the ever progressive America which brought this surgical colossus to the heights he attained. The lesser but still great achievements of his kinsmen in Ireland may be attributed in a measure to the fact that the same blood flowed through the veins of all.

In an address by Dr. W. R. Bett of London, entitled *Clio by the Bedside*, dedicated to Sir Humphrey Rolleston "because he liked it," it is pointed out that the elaborate edifice of modern medicine has not sprung up from the ground like a mushroom in the night. Each generation has put its hand to the task, has toiled and labored to complete its superstruc-

ture Its bricks represent the years its floors the centuries

More bricks and more floors will be added by future Murphys throughout the years and centuries that are to come

The exploration goes on The explorers wonder as of old what comes next and what part they are to play In their dreams they see Valhalla The spirits of their surgical forefathers are beckoning them to the land where dreams come true The work will continue when we have shuffled off this mortal coil

*And only the Master shall praise us and only
the Master shall blame
And no one shall work for money and no one
shall work for fame
But each for the joy of the working and each
in his separate star
Shall draw the thing as he sees it for the God
of Things as they are*

Those who have paid homage to Murphy at these great assemblies in past years have alluded specifically to some branch of his work, and some have recorded their own experiences in surgery in order to emphasize their indebtedness to his teaching

The scope of Murphy's writings is so wide that each successive speaker has been able to find a path which covers new ground By referring to individual and detached cases I will endeavor in some small measure to follow this precedent.

I must confess that it is difficult to obtain the end results of any large series in Ireland In the first place, we have a multiplicity of small hospitals in Dublin each completely detached from the other In the second place, our Gaelic temperament is such that patients consider it is ungenerous to admit of any suffering whatever, when inquiry is made for the purpose of statistics to be published abroad

Some years ago I wrote to a country practitioner to ascertain the end results of cases of gastrectomy I explained to him that the information was needed to compare the results from Dublin, with those of other countries, at an annual meeting of the British Medical Association His reply dictated more by patriotism than accuracy indicated that the

patients were well in every respect when last he saw them but that in some mysterious manner they had disappeared one by one from the district He added that as the country was disturbed they must have been shot, "or died from other natural causes"

SURGERY OF THE BLOOD VESSELS

Pupils in the Hunterian School shared in the enthusiasm of their teachers and the surgery of the blood vessels became a favorite subject of research and of practice during the opening years of the last century

The teaching of John Hunter was carried across the Atlantic by Wright Post to New York by Physick to Philadelphia, by Gibson to Baltimore and by Warren to Boston One surgeon alone—Valentine Mott ligatured the common carotid forty three times the external carotid once the first part of the subclavian once and the third part of the subclavian four times It is no matter of surprise says D'Arcy Power that the tradition of the surgery of the blood vessels is stronger in the United States than it is in this country Professor Rudolph Matas has nobly maintained the tradition at New Orleans by his reparative treatment of aneurism which is based upon experimental surgery in the true Hunterian spirit

Murphy was at home in the realm of vascular surgery In the year 1896, he performed the first recorded end-to-end suture of a divided artery His description of how he approached a false aneurism of the axillary artery by division of the clavicle and ligation of the subclavian artery is a noteworthy contribution to his surgical records

He paints a dramatic picture of a case of aneurism of the internal carotid artery mistaken for a tonsillar abscess Listen to him speaking "First a few clots of blood slowly wriggled their way out, and a little faster a few more Then came the rush of the arterial current with the full force of the spurting carotid The patient strangling in his own blood struggled wildly, and his friend ran away in a panic, an abject deserter Before Dr Lee could gain control of the patient the latter had bled to death and the office was like

a shambles from the struggle. Then comes the mention of thirteen different forms of treatment for aneurism and finally the statement that no surgeon should start the active practice of surgery until he has done a considerable amount of experimental work on the arteries and veins of dogs. After complimentary references to the operation of Matas he concludes an interesting discourse with the remarks "We Americans are little inclined to be Chauvinists. We are pretty apt to take what is good where we find it and if we owe a great debt to foreign medicine, it is because we have had the breadth of vision and unbiased minds necessary to profit from it.

Ligature of the innominate artery for right subclavian aneurism. In May last I ligatured the innominate artery for aneurism of the subclavian artery involving the first and second stage. The patient was wounded in 1915 pieces of shrapnel were shown by X rays, scattered in the region of the right shoulder joint, and portion of a bullet could be felt to the right of the suprasternal notch under the insertion of the sternomastoid muscle. The wall of the artery was apparently injured but the aneurism did not become evident until 1928 13 years after the wound. It steadily increased in size until the swelling above the clavicle reached the size of a duck's egg. The right recurrent laryngeal nerve was paralyzed. The radial pulse was not affected the blood pressure was the same on both sides. The X rays demonstrated some calcification within the sac. The Wassermann reaction was negative.

In some respects this tumor was not typical of aneurism there was no bruit expansile pulsation could not be detected there was no difference in the carotid or radial pulses when compared with those of the other side.

An operation was designed to ligature the subclavian artery behind the scalenus anticus muscle at the commencement of the second stage. The middle portion of the clavicle was turned downward on the chest with its pectoral attachments. The aneurism was laid bare and the bullet was removed. The external and internal jugular veins were found obstructed and distended. The supraclavicular and transversalis colli arteries spread transversely across the upper portion of the tumor

The scalenus anticus muscle had disappeared and the phrenic nerve was not located. It was soon seen that the sac extended to the bifurcation of the innominate artery and that ligature of the subclavian vessel was impossible. It was obvious that without further removal of bone the innominate artery could not be exposed behind the sternoclavicular articulation without the rough handling of the aneurism, which had led to disaster in many recorded cases. With chisel and mallet, the inner end of the clavicle together with the right half of the manubrium sterni (leaving the sternoclavicular joint intact) were separated and retracted upward and to the left. The innominate artery was now visualized in its entire length. The innominate veins were not seen the pleura caused no embarrassment, the nerves remained hidden.

Two ligatures of No. 2 chromicized catgut were passed around the artery distal to the thyroidea ima branch. They were gradually tightened care being taken not to cut through the inner coats of the vessel. Pulsation at once ceased in the aneurism and the radial pulse disappeared. Proximal to the ligature each pulsation appeared like a sledge-hammer blow upon the occluded portion. It looked as if the assault could not be resisted. For this reason, an additional single ligature of catgut was placed around the artery near its origin from the aorta. The thyroidea ima was ligatured with fine silk. The divided portions of the sternum and clavicle were replaced in position and held by catgut passed through drill holes. Recovery was uneventful but for some downward displacement of the divided portion of the clavicle.¹ In 3 days the radial pulse reappeared and within a week it was full and synchronous with the pulse on the opposite side.

The experience of this case suggests that ligature of the innominate artery is not a difficult operation provided the old inadequate methods of approach are abandoned. Six weeks after ligature some slight pulsation could be felt in the aneurism, but otherwise the cure appeared complete.

¹Four months after operation the aneurism had completely disappeared. Very slight pulsation could be felt at the site of the original tumor.

Up to and including the year 1922, according to Ballance, there had been 57 ligatures of the innominate artery with 19 recoveries.¹

A case of ligature of the innominate artery was exhibited by Mr Coppinger of the Mater Hospital, Dublin at the Section of Surgery of the Royal Academy of Medicine in Ireland, on February 24 1893. The record states that this was the first successful case of ligature of the innominate artery ever exhibited at any medical society in Europe.

The ideal operation for subclavian aneurism is excision of the sac after proximal and distal ligature. This has been successfully performed by Moynihan² by Halsted³ who removed with the aneurism a portion of the subclavio-axillary vein and also by Braithwaite.⁴ The possibility of ligaturing either the first or second portion of the artery is a condition precedent to excision. Both portions were involved in the sac in the case I have just mentioned.

In a volume⁵ on the works of Colles by Robert McDonnell, who was president of the Royal College of Surgeons in Ireland in 1877, the operation of tying the subclavian artery is admirably described. Colles attempted more than once to ligature the first stage of the artery, a far more difficult procedure than ligation of the innominate. He thought that ligation of the first stage on the left side was almost an impossibility, but A. K. Henry⁶ has shown that this operation is greatly simplified by an approach from behind.

Thoracic aneurism treated by wiring. Some years ago (1928) an ex soldier was admitted to hospital with an aneurism protruding through the chest wall to the right of the sternum below the clavicle. It appeared on the point of rupture. The heart and aortic arch were shown in the X-ray films to be greatly enlarged. It was thought that rupture might be delayed by consolidation if a wisp of Colt's wire was introduced. A month later the end of the wisp at the point where the wires are joined, became superficial and later ulcerated

Fig. 1. From a snapshot picture of Dr. John B. Murphy and Mrs. Murphy taken in the garden of Sir Robert Jones, Liverpool, in 1915.

through the skin. The junction was nipped with pliers and all the strands of wire were removed from the aneurism. Three months after operation the patient died from gradual leakage into the mediastinum and pleural cavity? No postmortem was obtained.

Abdominal aortic aneurism. America holds the world's record for thoracic aneurism treated by wiring and electrolysis. Colt states that Dublin holds the record for abdominal aneurism treated by wiring alone.⁷ In August 1910, a patient with a large abdominal aneurism in the region of the celiac axis was treated in Mercer's Hospital by the introduction of a cage of Colt's wires (150 inches) into the sac. He died suddenly on March 31, 1928, approximately 18 years after operation. The doctor in attendance reported that there was no abnormality of pulse or temperature or signs of internal hæmorrhage when he saw him just before death, but no postmortem was obtained.

In a second similar case, a wisp of 105 inches of wire was introduced into the sac of

These cases are described by kind permission of the Director General Ministry of Pensions.

the aneurism. After operation the man was passed as sound for service during the War as a stoker on a patrol trawler in the Naval Reserve. He died of leakage from a secondary dilatation of the aorta below the aneurism while thus serving, 4 years and 8 months after operation. At postmortem examination the aneurism was found completely consolidated. It was about the size of a full time fetal head. The wires had expanded uniformly. The specimen is preserved in the Surgical Museum of Trinity College.¹

I am indebted to Surgeon H. E. Kling Fretz, R.N. for the following notes on postmortem examination. Case 2.

"The patient, aged 37, a stoker R.N.R. on one of the patrol trawlers, was admitted into the Naval Hospital on March 12, 1916. He complained of vomiting and severe shooting pain in the right lumbar region simulating renal colic. There was tenderness in the region of the appendix and pain on deep inspiration. He was sweating freely and in a state of collapse. There was a large pulsating tumour which practically occupied the whole of his

epigastric region, apparently an aneurism of the abdominal aorta. His temperature was 99° F, pulse 120, full and regular, systolic pressure 240 mm., diastolic pressure 120 mm. His urine showed a heavy deposit of urates and a trace of albumin. There was an excellent scar to the left of the midline 3 inches long, the result of operation five years ago. A systolic bruit could be heard over the swelling, propagated all over the abdomen and down both femoral arteries. There was a marked diastolic sound in the mitral area and a very accentuated second sound in the aorta. Seven days after admission he died. The swelling continued to pulsate long after respirations had ceased.

"At the autopsy it was found that there was a small leak, the hemorrhage penetrated between the layers of the mesentery separated them widely apart, and surrounded a large portion of the small intestine. The right kidney was pushed forward. Both kidneys and spleen were normal in size, the right kidney having small granular patches on the surface. The heart was much enlarged. Now for the aneurism, I am not exaggerating when I say that the clot formed in it is as hard as a rock, the aneurism itself is about the size of a full term foetus head. It appears to me as if there is a secondary dilatation of the aorta below the main swelling and that is where the trouble arose.

Fig 4. Northumberland House Strand, London. Butcher, in July 1838, describes how under perilous circumstances he succeeded, with the aid of a rope in climbing on the back of the lion

I am also indebted to Surgeon King Fretz for the specimen which is illustrated in Fig 1 and for the X-ray photograph showing the wire *in situ* (Fig 2)

The abdominal aorta was first ligated by Sir Astley Cooper. In 12 cases recorded subsequently, the mortality was 100 per cent. Nevertheless ligation below the renal vessels has been followed by success. Brookes¹ described and illustrated a case in which the patient died of intestinal obstruction 3 months after successful ligation. The prognosis of abdominal aneurism without operation is unfavorable. The duration of the condition is said to vary from 3 months to 3 years.

Aneurism of the popliteal artery. How the more modern conception of the surgery of the blood vessels comes to our assistance may be illustrated by a case of popliteal aneurism in a man aged 62 years. The aneurism was the result of a slight injury and had reached the size of a coconut. It had extended upward from the popliteal space to the opening in the adductor magnus. The patient was a bad surgical risk. He was fat and short necked. His heart was fibrillating, his systolic blood pressure was 220, his pulse rate 140. His foot was cold and

gangrene was impending. The old operation of ligation of the femoral artery would almost certainly have been followed by gangrene. An extensive operation on the sac or amputation in all probability would have been followed by death. A complete cure with restoration of the circulation in the limb followed resection of 1 inch of the artery in Hunter's canal and ligation of the femoral vein.²

Resection of the artery is a radical form of sympathectomy and in this case produced increased heat and blushing of the foot. The sheath of the artery above and below the ligatures was injected with alcohol as recommended by Sampson Handley to ensure against transitory vasoconstriction.

The advisability of ligaturing both artery and vein or the vein alone, when there is a dangerous diminution of the blood supply to a limb has only been recognized since the War. This recognition, reinforced by a better understanding of the surgery of the sympathetic nerves, has saved many limbs in recent years.

THE SYMPATHETIC NERVOUS SYSTEM

The assaults brought about by an unbalanced sympathetic nervous system have been

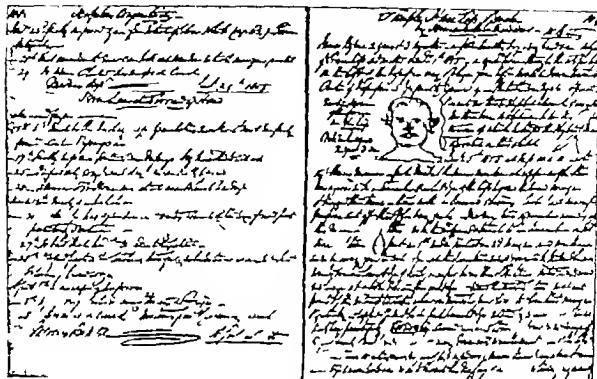

Fig. 5 Page from one of Butcher's voluminous case books, describing his operation for bare-Ep.

countered by the surgeon in many fields. Pylorospasm and megacolon can be cured or relieved spasm of the vesical sphincter causing urinary retention is coming under control pelvic pain *per se* disappears under the magic wand of sympathectomy.

Raynaud's disease can now be conquered and certain forms of polyarthritis have yielded to sympathetic resection.

HIRSCHSPRUNG'S DISEASE

This is a rare condition. I have had 2 cases under my care in 10 years. The colon may contain as much as 47 pounds of feces, the circumference of the bowel may reach over $3\frac{1}{2}$ feet. The bowels may act only once in 2 or 3 weeks and in some cases several months have elapsed without an evacuation. Until the discovery of the rôle of the sympathetic in this condition physicians ordered surgical treatment, surgeons recommended a medical regimen.¹ In one third of the cases the sigmoid flexure alone is involved and excellent results

can be obtained by the simple operation of removal of the left sympathetic chain by a trans-pentoneal operation. The removal includes the second, third and fourth ganglia.

In my second case the limited operation proposed by Rankin and Learmonth was performed (February 1931). The child was aged 2 years. The pelvic colon when the abdomen was opened had the appearance and consistency of a small motor car tire.

In this case there was one unusual feature. The pelvic colon was not dilated for 2 or 3 inches above the pelvi-rectal sphincter and the rectum was normal. X-ray photographs taken before operation showed an enormous loop of descending colon. The barium meal was visible a week after ingestion, notwithstanding repeated washing out of the colon. The barium enema also revealed an enormous colon, five or six times the normal diameter. The ascending colon was not dilated, and the transverse only moderately so.

The posterior pentoneum was divided from the promontory of the sacrum to the origin of the inferior mesenteric artery. The preacral nerve and its branches in the infant were not easily defined, but communicating filaments from the second, third,

Fig. 6. Subclavian aneurism showing the bullet and calcification in the sac.

and fourth sympathetic ganglia were divided and the area cleared of loose connective tissue. The inferior mesenteric artery near its origin was similarly denuded but no very definite ganglia were found. The operation was rendered more difficult

Fig. 8. Thoracic aneurism from which wires were removed a month after introduction.

Fig. 7. Ligation of the innominate artery. The operation was planned at first for ligation of the subclavian artery but was modified later to ligation of the innominate artery. *A* Transversalis coli; *B* external jugular vein; *C* supra scapular; *D* portion of sternum and clavicle retracted; *E* innominate artery. Inset shows ligatures proximal and distal to the thyroidea ima branch.

by the attachment of the mesocolon to the right of the middle line.

We had some difficulty in deciding whether we were dealing with tiny lymphatic vessels and glands instead of nerve fibers and ganglia in the course of the operation. In an infant I am not sure that frank exposure of the lumbar sympathetic chain on the left side and division of the trunk above the second and below the fourth ganglion would not

Fig. 9. Side view of aneurism. The line marks the point of rupture. (One half natural size.)

Fig. 10. Postmortem roentgenogram of abdominal aneurysm 4 years and 8 months after operation. Coll's wires are seen in the sac.

be the more satisfactory operation ramsection being performed at the same time.

The boy's constipation was completely relieved by the operation, and this relief has continued. After operation a full sized sigmoidoscope was passed through the pelvi-rectal sphincter on a few occasions, the colon being emptied by means of an irrigating tube. Two months after operation a barium meal and enema demonstrated the pelvic loop of colon still dilated, but greatly reduced in diameter. The transverse colon was also considerably reduced. Seven months after operation dilatation was still present, but there was slight further improvement. The umbilical girth at the time of operation was 33½ inches. Five days later it was 21½ inches.

KIDNEYS AND PROSTATE

It has been pointed out that Murphy in his lectures on the surgery of the urinary tract laid great emphasis on the significance of back pressure in cases of prostatic obstruction.

Success depends on the relief of this back pressure and it is an accepted fact that this relief must be gradual. Back pressure renal insufficiency, cardiovascular changes and uremia, go side by side as time advances with prostatic enlargement. It is traditional that

sudden decompression either by uncontrolled cystotomy or by primary prostatectomy is followed by a recoil carrying a high mortality. The engorgement of the kidneys on sudden release of pressure is not surprising when we remember that the whole of the blood of the body passes through the kidney every few minutes. The other side of the picture shows the reparative phenomena which follow gradual decompression. Renal cells, like hepatic cells, and myocardial cells, have a definite power of regeneration if the causes producing degeneration are removed. In old standing cases, some of the kidney is irreparably damaged, some is damaged but is capable of regeneration and there is probably a residue in most cases which has not yet become embarrassed.

In cases of overdilatation of the bladder the path of safety is not the inserting of a catheter and the withdrawal of small amounts

Fig. 11. Hirschsprung's disease. Condition of the descending colon before operation. Note the radiated loop of pelvic colon below.

of urine every few hours. A few ounces (100 cubic centimeters) of urine, withdrawn from a distended bladder, may induce renal and circulatory shock.

For many years in Mercer's Hospital we have gradually decompressed distended bladders by allowing the urine to flow drop by drop by means of a reversed Murphy drip apparatus attached to an in-dwelling catheter. If this apparatus is not at hand a rubber catheter is passed. It is clamped or plugged at the end to prevent urine escaping. A hypodermic needle is inserted through the rubber wall of the catheter, and through this needle the urine drips slowly until danger is passed. An ureteral catheter passed into the bladder acts in the same manner.

The necessity for gradual decompression is not confined to the urinary tract. The same problem arises when we are dealing with medical problems such as high blood pressure.

Fig. 13. Child aged 2 years six months after conservative sympathectomy for Hirschsprung's disease. The constipation is cured, the distention is reduced (girth of abdomen at operation 23½ inches now 21½ inches) but persists.

It confronts us when there is back pressure on the liver, it is a factor in cases of ascites and intestinal obstruction. It faces us again in cerebrospinal lesions in acute empyema, in hydrocephalus, hæmatocolpos and glaucoma. Thus medicine, surgery, gynecology, and ophthalmology are all concerned in the fatal significance of a severe recoil following sudden decompression.

The general problem so far as treatment is concerned might, I think, be expressed as follows, in the terms of a law. *When an organ or system is suffering directly from pressure effects or indirectly from back pressure the greater the pressure the more gradual should be its relief.*¹ Hippocrates indeed drew attention to this fundamental consideration in the following aphorism given to me by Dr T. P. C. Kirkpatrick:

ἀκόσμοι ἑμψυχοὶ ἢ υδρωπικοὶ τέμνονται ἢ καλοῦνται ἐκρίναι τοῦ πύου καὶ τοῦ ἰσχυροῦ ἀθρόου πάντως ἀπολλύονται.

"Purulent or hydropsical cases who are lanced or cauterized, water and pus flowing out together, perish completely." (Aphorism of Hippocrates Sect vi, No 27.)

¹Wheeler: *Canada M. Ass. J.* 1931 III 8.

Fig. 12. Hirschsprung's disease. Condition of colon six months after operation.

Fig. 14. Recurrent prostate. The prostate was removed with "cure" of patient. Symptoms recurred 23 years after operation. Examination revealed advanced obstruction from a regrowth of the gland. It was removed piecemeal a second time by enucleation and dissection. The illustration shows the second prostate.

RECURRENT PROSTATE

Recently I had under my care a man aged about 75 suffering from advanced uremia the result of prostatic enlargement. The prostate had been removed 12 years previously by Sir Conway Dwyer in the Richmond Hospital. For 12 years after operation he was completely relieved, but after this period the old signs and symptoms of prostatic enlargement gradually

recurred until finally the residual urine was at the maximum and by chemical tests renal destruction was almost complete. A greatly enlarged prostate could be felt per rectum.

This was a case of recurrence of simple enlargement of the prostate. The condition is referred to by Sir John Thompson-Walker in the Lettsomian Lectures delivered before the Medical Society of London.¹ This writer draws attention to a number of cases in which the prostate appears to have been reconstructed after prostatectomy.

In the case I have just mentioned gradual decompression and subsequent drainage for 6 months secured a sufficient return of renal function to permit a second prostatectomy. This was accomplished partly by enucleation and partly by dissection. The final recovery was complete.

SOLITARY CYST OF THE KIDNEY

A cyst surrounded by renal substance was removed from the upper pole of the right kidney of a woman aged 57 years, in September, 1931. Painless hematuria and the presence of a smooth, painless enlargement of a right mobile kidney were the outstanding clinical features. Pyelography revealed the upper calyces occluded and deformed, and slight hydronephrosis on the left side. Biochemical

Fig. 5. Solitary cyst removed from the upper part of the kidney with surrounding renal parenchyma.

Fig. 16. Congenital laryngocele. *A* Air containing protrusion on the dorsum of the tongue, *B* tip of tongue deviated but could not be protruded. *C* communicating air sac in the submaxillary region. Illustration was made from the patient before death.

Fig. 1. Congenital protrusion of a laryngeal pouch. Drawing from a specimen in Trinity College Dublin, by kind permission of Professor A. F. Dixon.

investigation showed a high blood urea 72 milligrams per cent, the urea concentration test revealed an excretion of 1.5 per cent urea 3 hours after the meal.

The cyst was about the size of a tangerine orange. On exposure, the kidney was found quite normal but for the upper pole which was involved in the cyst. It was removed by a wedge-shaped incision into the kidney substance. The cut renal surfaces were brought together by interrupted Halsted's stitches. The stitches were prevented from cutting through by the interposition of portions of detached muscle after the manner recommended by Walters. Recovery was uneventful.

Solitary cysts of the kidney are rare. Fullerton¹ says that up to the time of writing (1926) only 99 cases had been reported.

LARYNGOCELE

Murphy excelled in the realm of diagnosis. He could separate the essential from the non

essential factors with great rapidity and in a short time what appeared to be a complex tangle of contradictory signs and symptoms was straightened out and made simple.

The case to which I now draw your attention puzzled us considerably but by applying the inductive methods of reasoning adopted by Murphy its nature was finally made clear.

The patient was a man aged 24 years, who suffered all his life from a painless bulge or swelling in the right submaxillary region. This swelling was tympanitic and under pressure disappeared. The swelling moved and protruded with deglutition or coughing. The right side of the tongue and floor of the mouth were enlarged. On the posterior third of the dorsum of the tongue on the right side there was a soft conical projection about the size of a small lump of sugar. The tongue could not be protruded. Any attempt to do so resulted in deviation of the entire organ to the right side. Speaking was difficult. It was owing to the fact that his friends could not understand what he said that he came to hospital to seek advice. The swelling on the tongue and the swelling in the submaxillary region were connected. If the one was pressed upon, the other enlarged. It was obvious that the swellings were not solid, nor did they contain fluid. The introduction of a hypodermic needle into the protrusion on the tongue gave no information. After the injection

Fig. 18. Laryngocoele, lateral view. The protrusion on the tongue was injected with 10 cubic centimeters of lipiodol. Note the narrow connection between the lingual and submaxillary portions.

of lipiodol through the needle. X-ray photographs confirmed the fact that the tongue swelling and the submaxillary swelling were connected.

At this stage, the true condition was not realized. With a view to operative exploration, the patient was given cocaine ether. He died suddenly before anesthesia was produced.

On searching the literature the first clue to the nature of this case was obtained from a paper on malformation of the larynx by E. H. Bennett published in the *Dublin Quarterly Journal of Medical Science* vol. 40 1865. Bennett was the first to discover a human larynx in which there existed fully formed laryngeal pouches which are normally found in a high state of development in some of the higher apes.

Bennett was dissecting in the region of the thyroid cartilage in Trinity College. His attention was arrested by a cystic structure which he opened accidentally on one side. A probe passed downward through the opening into the larynx. At first he thought that the condition was the result of disease but he found a similar sac on the opposite side. Further investigation showed that the pouch occupied nearly all the space which is covered by the thin lateral portion of the thyrohyoid membrane. The lower border of the protrusion rested on the superior laryngeal vessels and nerve and superiorly was in contact with the under surface of the great horn of the hyoid bone. On examining the interior of the larynx the probe passed through the sac from without, beneath the anterior part of the false vocal

Fig. 19. Laryngocoele, anteroposterior view. Note the trickle of lipiodol toward the lateral wall of the larynx.

cords. It entered the ventricle of the larynx by an opening of oval shape, about three-fifths of an inch in length. The opening corresponded to the sinus of Morgagni.

Professor A. F. Dixon, professor of anatomy in the University of Dublin kindly showed me another specimen from which the drawing (Fig. 17) has been made.

There is little doubt that the patient to whom I have referred was suffering from this congenital deformity. The appendix of the laryngeal ventricle on the right side had extended through the thyrohyoid membrane in an upward direction behind the body of the hyoid bone to the floor of the glosso-epiglottic fossa.

There is no mention in surgical literature of the extension of these extra laryngeal pouches into the tongue. In the apes they extend down the neck, often as far as the clavicle or

Fig. 20 Multiple lesions. Patient's breast removed for cancer 5 years ago. Thought to be suffering from metastasis. Investigation revealed bilateral renal calculi and simple ulcer of the lesser curvature of the stomach: gastrectomy: recovery.

between the two heads of the great pectoral muscle into the axilla. They attain a very large size.

Von Bergman¹ mentions laryngocele and congenital air cysts in connection with swellings of the neck. He and other German writers refer to the danger of sudden death from suffocation when the sac becomes overdistended.

The fact that the lipiodol did not enter the larynx in the case under review may be explained on the hypothesis that the interior opening was either very minute or of a valvular nature.

In his *Anatomy*,² Quain states that the blind end of the appendix sometimes passes upward, lateral to the aryepiglottic fold and behind the body of the hyoid bone, so as to lie close to the floor of the glosso-epiglottic fossa. In this volume reference is made to Slavunas who collected reports of 10 cases of congenital

Fig. 21 Same case as in Figure 20, showing the large branching renal calculi.

laryngocele. Two were bilateral, 4 were unilateral and 4 were bilateral but with a larger sac on one side.

Andre Forster, professor of medicine in Strasbourg, gives a very full illustrated account of the laryngeal sac in apes.³

MULTIPLE LESIONS

It is like pushing an open door to mention to an assembly such as this the necessity for complete and thorough examinations in all cases, but diagnostic endeavor in small surgical centers has a tendency to become concentrated and focused on one prominent lesion. If a patient is found after examination to be suffering say from duodenal ulcer, it is forgotten that gastric ulcers may also be present and the case further complicated by disease of the pelvic organs, the kidneys or the gall bladder.

I have been struck with the number of patients who come for operation suffering from cholelithiasis who were found to have a midline scar below the umbilicus for the correction of what was believed to be some uterine or ovarian disease. This scar has so frequently been in evidence (in fat women who have borne children) that many students in Dublin regard it as supporting evidence of the diagnosis of biliary stones.

Fig. 22

(Figs. 22-25 from Brit. J. Surg., 1921, 34.)

Fig. 25

An interesting case with multiple abdominal lesions was admitted to Mercer's Hospital in October 1931.

She was aged 56. Five years previously her breast had been removed for carcinoma. She had lost weight she was anemic, and she suffered from constant pain in her upper abdomen. Metastatic growth was diagnosed without full investigation in the first instance. X ray photographs showed a chronic penetrating ulcer in the lower curvature of the stomach. Cystoscopy revealed that the urethral orifices were normal but that pus was flowing in large quantity from the right side. The blood urea was high. The urea concentration test after 5 hours gave a 1 per cent excretion. Further X ray photographs demonstrated large branching calculi in both kidneys. The middle portion of the stomach was removed under gas oxygen and local anesthesia. The ulcer was found to be non malignant and the patient made a rapid recovery. No doubt uremia will eventually supervene, but for the moment her pain is gone, and the dread of cancer has been stilled.

Finally I will mention 2 cases one of bone grafting to replace the upper end of the humerus and the other arthroplasty for ankylosis of both knees. The operations were performed exactly as Murphy dictated and the results

Fig. 26. Right knee joint ankylosed in extension.

Fig. 27. Left knee joint ankylosed in flexion.

obtained were entirely due to the doctrines he preached

Figure 22 shows a soldier aged 25 who was wounded toward the end of the War. The right shoulder below the acromion process was carried away *en masse*—skin, muscles and bone. Only a pedicle remained on the inner side carrying the main vessels and nerves by which the arm hung helplessly to his side. All scar tissue was cleared away and the upper end of the bone was freshened. A bone-graft 9 inches long taken from the tibia was driven for 4 inches into the medullary cavity. The upper portion was placed in contact with the glenoid cavity. Three months

Fig. 30. Snapshot of child walking, right knee.

Fig. 31. Snapshot of child walking, left knee.

(Figs. 26-31 from Brit. J. Surg. 1921 ix, 34.)

later the graft had thickened but there was loss of density in the picture owing to the destructive powers of the osteoclasts being more apparent in the X rays than the regenerative powers of the osteoblasts. Six months after operation firm bony union was shown at the upper end of the new humerus. The intramedullary portion of the graft has become partially absorbed. Nine months after operation strong new bone had replaced the slender original graft. Fourteen months after operation

Fig. 28. Amount of voluntary flexion in left knee joint 2 years after operation. Note the patella "turned turtle."

Fig. 32 Lateral and anteroposterior views of patient with bullet in the association area of the brain

although movements of the shoulder were limited, the strength of the arm left nothing to be desired.⁴

After five years an X-ray photograph shows the humerus completely reformed (Fig. 33)

ARTHROPLASTY

The accompanying illustrations (Figs. 26-31) show the result of Murphy's arthroplasty in the case of a girl aged 11 years operated upon in September 1919.⁶

FOREIGN BODY IN THE BRAIN

The following case is mentioned because the history given by the patient is picturesque and because it is unusual for a bullet to enter the brain without the patient knowing that he had been severely injured.

A patient aged 31 was wounded in the head in May 1921 while engaged in street fighting in Dublin. He received what he believed then to be a small scalp wound to the right and above the occipital protuberance. He was dressed but not detained in the hospital. No X-ray was taken. He noticed at the time of his wound sounds of music in his ears as if there was a band with drums in close proximity. A fortnight later he was smoking a cigarette when a black dot appeared in his right lateral field of vision. The speck moved medially, growing larger and becoming bright until it appeared as a blinding light in the center of his visual field.

At this stage he became totally blind. He never lost consciousness, but his memory was stimulated and distorted. He imagined he saw men firing at him, while he was surrounded by comrades. Head ache and vomiting supervened. These aurial attacks lasted about 30 minutes and recurred once or twice a month for 4 years. In the intervals he was well, and led an energetic life, but the reappearance of the black spot when least expected like the ghost of Hamlet left him morbid and alarmed.

Clinical examinations were entirely negative there was no paralysis, motor or sensory, no alterations in the reflexes, and both fundi were normal.

X-ray examinations disclosed that the nickel case of part of a conical bullet was lying in the base of the brain just behind the petrous portion of the temporal bone at the level of the eminence in the superior semi-circular canal. To approach the bullet in a direct line it would have been necessary to open the skull behind the vertical line dividing the mastoid into equal parts. The direct route would have led through the sigmoid portion of the lateral sinus and some of the posterior branches of the middle meningeal artery.

Operation December 10, 1925. The skull was opened at a level above the location of the bullet, and when the meninges were divided, a finger was passed under the temporal lobe in front of the cerebellum. After some difficulty a feeling of resistance was detected with the finger, and with the latter *in situ* a forceps was pushed through the temporal lobe from above. A mass about the size of an olive was located and was enucleated. There was a line of cleavage between the mass and the brain substance. On removal the tumor proved

⁴Wheeler Brk. J. Surg. 91 12, No. 24.

⁶Wheeler Brk. J. Surg. 91 12, No. 24.

to be composed of fibrous tissue encapsulating the conical point of the bullet. Before it could be extracted it became necessary to nibble away bone toward the base of the skull. The sigmoid portion of the lateral sinus was wounded but the control of bleeding was not difficult.

During the removal, some brain matter on the lateral surface of the temporal lobe was injured and removed. In bulk the brain matter sacrificed was about the size of the tumor.

The after history was uneventful. A month after the operation the patient appeared quite well. He had no recurrence of his previous attacks.

Before operation a model of a brain was placed in a skull and with the aid of the X rays it was possible to map out the exact position of the foreign body encapsulated in the fibrous mass. It lay underneath the junction of the temporal and occipital lobes. The area involved was the association area which lies between the visual area behind and the portion of the brain concerned with hearing in front.

It was interesting to correlate these findings with the clinical history given by the patient. There were just three points in the history: (1) The sounds of hand music on the day he was wounded. (2) The distorted visual phenomena occurring on an average twice a month for over 4 years. (3) The memory of troops firing at him while he was surrounded by his friends.

It may be surmised that the association area in the brain from which the foreign body was extracted is one of the resting places of the intellect which brought to memory hearing and sight. It is the development of such a center (absent at birth and in the lower animals) which accounts for the fact that Beethoven was able to write and conduct his beautiful symphonies at a time when he was overwhelmed with deafness and deprived of the faculty of which he stood most in need.

AN EXPERIMENTAL AND CLINICAL STUDY OF THE USE OF RADIUM IN THE BRAIN¹

LOYAL DAVIS M.D., F.A.C.S., AND MAX CUTLER, M.D. CHICAGO

From the Department of Surgery Northwestern University Medical School and the Tumor Clinic of Michael Reese Hospital, Chicago

THE many accomplishments of neurological surgery in the past thirty years have been made in the fields of surgical technique, diagnosis, and pathology. The perfection of the meticulous details of an osteoplastic craniotomy with complete hemostasis particularly during the removal of a tumor, replacement of the bone flap, and an accurate wound closure without drainage was the first important contribution. Attention was then turned to matters pertaining to diagnosis. Today the time has passed when headaches, papilloedema, and vomiting must be present before the diagnosis of an intracranial tumor may be made.

Of equal if not of greater importance than these matters was the microscopical verification and classification of the tumors exposed and a correlation of the pathological picture with the clinical course of the patient before and after operation. Today the neurological surgeon must be able to foretell not only the precise situation of the lesion but its probable pathological character as well.

Though remarkable progress has been made, there are still many intracranial tumors which cannot be removed completely by surgical means. This is particularly true of the gliomata which constitute about 45 per cent of all intracranial tumors. The correlation of the pathological and clinical characteristics of this group of tumors has made their subdivision possible, so that we are now cognizant of the difference in malignancy between the astrocytomata on the one hand and the glioblastomata on the other. However the present surgical methods employed which consist of removal of the tumor by suction, by resection of large portions of the hemisphere, or by the electrosurgical scalpel are not completely satisfactory. All of these methods entail a large surgical risk, a gross destruction of brain tissue with the possibility of many neurological residual symptoms, and finally there is the possibility of leaving tumor tissue behind.

There should be no question that any suggestion for improvement in therapy must be based upon surgical exposure of the tumor and its microscopical verification. Any therapeutic agent which could be employed so that the tumor might be inactivated *in situ* without destruction to surrounding normal brain tissue, would be a progressive step in the surgical therapy of the gliomata. The use of radium implanted directly into the tumor suggests itself immediately.

Danyss (6) was probably the first to study the effects of radium upon the central nervous system. In 1903 this investigator placed a radium bearing tube 1 centimeter in length over the spine and part of the skull of a mouse 1 month old. Within 3 hours the animal developed paralysis and ataxia; after 7 hours, convulsions; and 18 hours later the animal died. Mice 1 year old exposed in a similar manner died 6 and 10 days later. Three guinea pigs 8 to 12 days old in which the same radium tube was placed beneath the skin over the lumbar cord for 24 to 48 hours developed complete paralysis of the posterior part of the body after 1 to 3 days. Adult guinea pigs and rabbits treated in a similar manner showed no lesion of the spinal cord but succumbed 3 weeks later to infection. An adult rabbit exposed to the radium tube for 8 hours was normal for 2 days and then developed hemiplegia on the third day.

Later the same author (7) exposed mice confined in wooden cages to 23 milligrams and 50 milligrams of radium bromide which was fastened in a hole in the lid of the cage. The time of exposure varied between 4 hours and 30 days. The animals developed alopecia, dermatitis, and paralysis and some died. Microscopically the tissue showed vascular changes consisting mainly of ruptured capillaries, but no changes could be demonstrated in the nerve cells.

In 1903 London (11) exposed young mice in a small glass cage to 30 milligrams of radium

bromide fastened on the cover. All the animals died after 4 or 5 days. The symptoms were insomnia, restlessness, and weakness which was followed by paralysis and coma. At postmortem examination hemorrhages were present in the subcutaneous tissues and in the dura over the cerebral cortex. In subsequent experiments (12) he found atrophic nerve cells in the spinal cords of 3 rabbits which had been exposed for long periods to 25 milligrams of radium.

Heincke (9) found deep hemorrhagic areas with softening of tissues at the site of application in a rabbit which had carried 20 milligrams of radium bromide on its head for 14 days. The rabbit was well for 3 weeks and died suddenly with spastic symptoms.

An intense reaction in the meninges was observed by Scholtz (20) in rabbits in which 25 milligrams of radium bromide were fastened to the head for 1 to 3 hours.

Obersteiner (13, 14) observed large and small hemorrhages in the cerebrum, cerebellum, and medulla with perivascular round cell infiltration. The nerve cells remained unaltered in mice whose heads were exposed to diffuse radiation. The severity of the symptoms depended upon the age of the animals, the duration of the exposure, and the amount of radium used. The symptoms were for the most part a direct or indirect expression of circulatory and metabolic changes produced by the radium. Similar effects—punctate hemorrhages without changes in the nerve cells—were noted by Alquier and Faure-Baulieu (1) in the brains and the cords of rabbits which were exposed to external radium applications.

In 1911 Horsley and Finzi (10) placed 55 milligrams of radium bromide on the pre- and postcentral gyri of monkeys for $2\frac{1}{2}$ to 4 hours. The rays were filtered through 0.5 millimeters of platinum and 1 millimeter of rubber. None of the animals showed symptoms after 26 to 45 days when they were sacrificed. Examination of the brains showed thickening of the dura with infiltration of the pia and arachnoid by erythrocytes and leucocytes. There was an endothelial hyperplasia of the blood vessel walls in some places so marked as to occlude the lumen. The first

two layers of the cortex were the seat of punctate hemorrhages. No changes in the nerve cells were discovered.

Williamson Brown and Butier (21) placed 50 milligrams of radium element filtered through 0.4 millimeters of platinum upon the motor area of the cerebral cortex for 4, 6, 12, and 18 hours. They found that within a radius of 4 millimeters from the tube a 12 hour exposure caused complete destruction of brain cells and interstitial tissues. The blood vessels showed marked thickening and hyalinization without rupture of the walls. In a second zone 1 millimeter in diameter outside the former area the cells were not destroyed completely but showed distinct signs of degeneration. The authors concluded that 50 milligrams of radium acting for 18 hours produce a destructive effect upon the tissues within a radius of 5 millimeters. The effect upon the blood vessels varied with the dose and the distance from the radium focus.

Bagg (2) studied the effects of glass capillary seeds containing radon upon the mammalian brain. He found that the tissue in the immediate vicinity of the tube became completely necrotic. Surrounding this area was a zone of polynuclear leucocytes beyond which there was a zone of hyperemia. At the end of 24 hours the zone of necrosis was 1 millimeter wide. The maximum effect was reached at the end of 2 weeks when the lesion was 1 centimeter in diameter. Each glass capillary seed was 3 millimeters long, 0.4 millimeters in diameter, and 0.1 millimeter thick.

In an effort to study the functional rôle of the group of nerve cells composing the corpus striatum Bagg and Edwards (3) implanted similar glass radon capillary seeds into the corpus striatum of dogs. One tube was implanted into each dog by means of a trocar introduced through a 2 millimeters trephine opening into the skull. Six weeks after insertion there was a localized destructive lesion consisting of an inner area of necrosis 4 millimeters in diameter surrounded by a ring of fibrin and then an outside zone 2 to 3 centimeters wide which showed edema, and a rich cellular exudate. Microscopical examination of the lesion showed a central partly cystic area of softening discolored by methemo-

globin. In this area there was a collection of large round cells distended by fat droplets and yellowish granular pigment. The lesions were sharply demarcated and the surrounding brain tissue showed no alteration in structure.

Pendergrass, Hyman, House and Rambo (16) have studied the effects of radium upon the normal tissues of the brain and spinal cord of dogs, both by surface applications and implantation. The surface applications were made over the parietal cortex the radium tube being placed on the dura. In the implantation experiments two needles were inserted in each dog through an opening over the parietal lobe. Surface application was made with platinum or silver tubes of 0.5 millimeter wall thickness, 2.8 centimeters long and 3 to 5 millimeters wide. Steel needles used for implantation measured 2.8 centimeters long 1.5 millimeters wide and contained 10 to 12.5 milligrams of radium element. With external applications all of the dogs which received 1,150 milligram hours or less showed no symptoms. All of the animals which received 1,400 milligram hours or more died. Two of the dogs in which interstitial radiation was used developed general peritonitis and 1 developed meningitis from which they died. These same authors also found that an exposure to 600 milligram hours of radium over the spinal cord caused marked clinical symptoms. Areas of necrosis were found two segments above and below the lesion of direct contact. In addition to the local area of necrosis an increase in weight of the irradiated hemisphere indicated the presence of edema. The authors state that the cause of death in the dogs was not due to a local effect upon the brain but to toxemia. They noted that many changes were found following exposures which gave no clinical signs or symptoms, and they concluded that an exposure of normal brain tissue up to 1,150 milligram hours is compatible with life.

Carnes and Fulton (4) using cats and monkeys, implanted radon seeds 1.5 centimeters long with 0.3 millimeter platinum filtration alongside the spinal cord but extradural in the dorsal region. With large doses (31 millicuries) signs of weakness of the hind extremities appeared 30 hours after operation. The

paraplegia became complete 3 to 4 days after the onset. With smaller doses the time of onset of the first symptoms was later and the appearance of the complete paraplegia correspondingly delayed. In cats any dose greater than 9.5 millicuries produced complete paraplegia. Monkeys proved more resistant than cats because a dose of 12 millicuries produced only slight weakness. The first symptom exhibited was loss of the sense of position which was followed several hours later by motor weakness. The animals invariably passed through a stage of extension before developing a characteristic, complete flaccid paraplegia.

Carmichael and Ross (5) performed a series of experiments in which they placed radon seeds within and upon the dura mater and radium needles upon the dura mater. They used 5 millicuries of radon with 0.3 and 0.5 millimeters of platinum filters. The animals were sacrificed from 1 hour to 61 days, during all of which time the radon seeds or radium were in place. They concluded that following the use of radon seeds the endothelium of the blood vessels showed the first changes, then an emigration of leucocytes occurred, followed by local destruction of the cerebral cortex and finally hemorrhage. Fat was found in the blood vessels and after 94 hours thrombosis had occurred. Microglia cells loaded with fat were found in the subarachnoid space and in the perivascular spaces. The nerve cells stained poorly, neurofibrils were fragmented and the myelin sheaths were segmented and stained faintly. It was found that repair was evidenced after 212 hours of exposure by a proliferation of astrocytes. One half milligram needles of radium showed a very local effect. The authors reported that they had used radon seeds in 2 cases of pituitary tumor, 1 choroid plexus papilloma, 1 meningioma, 1 metastatic carcinoma and 3 gliomata.

Sargent and Cade (19) prefer the implantation of radium needles into tumor tissue but believe that interstitial radiation has a limited field because of the effect of radium upon blood vessels. These authors have used radium needles in several patients with intracranial gliomata and record dosages as large

as 3.721 and 5.184 milligram hours. They also used external, or surface irradiation with intermittent exposures of from 14 to 18 hours daily for 2 to 3 weeks or from 4 to 6 weeks if no interstitial radiation had been used. Three of the cases reported upon were oligodendrogliomata, a type of glioma which ordinarily has a good prognosis.

Ross (18) in a later paper has pointed out that radon seeds produce a local necrosis of cerebral tissue associated with hemorrhage and that radium element produces a more uniform radiation than radon. It would appear that Ross assumes that the changes produced immediately about the needle tract are due to the effect of radium.

The effects of implanting radium into brain tumors have been reported by various observers. In 1920 Frazier (8) reported 3 cases. The first patient was 13 years of age and had an inoperable tumor of the cerebellopontile angle. Eighty-five milligrams of radium were implanted in the tumor for 15 hours. Three years later there were signs of recurrence and a second radium implantation was performed. Six years after the first treatment the patient was still living and while symptoms of cerebellar disturbance were still present the condition was stationary. The second patient was a child with a serious disturbance of cerebellar function. A suboccipital decompression and radium implantation resulted in extraordinary improvement. Eight years after the treatment the child was reported to be in perfect health. There is no information upon the amount of radium or the technique employed in this case, and the nature of the tumor was not verified by microscopic examination. The third case was that of a patient 30 years of age who had been operated upon 19 months before admission because of disturbance in vision due to a pituitary lesion. Radium was applied to the pituitary body through the posterior nares. The treatment was followed by marked improvement and there was no evidence of recurrence 3 years later. The author mentions that in no instance had a glioma been benefited by radium treatment.

Pancoast (15) states that based upon the work of Pendergrass, the surface dose of radium to the brain over a limited surface area

Fig. 1. Diagram to show methods of exposing photographic films to the radium needle.

should not exceed 1,400 milligram hours though Frazier has given 1,445 milligram hours to a large cerebellar tumor without untoward results. He was of the opinion that radium implantation alone in safe doses is inadequate for the tumor and must be supplemented by external radiation.

Recent developments in our knowledge of radiation therapy have established certain fundamental principles that have an important bearing upon treatment. Thus it has become recognized that an optimum time interval exists during which a tumor reacts best to radiation. Exposure of the growth during a shorter period results in failure to gain a maximum lethal effect upon the tumor cells. Exposure over a longer period results in the establishment of a state of radio-immunity. The importance of utilizing the most penetrating rays of radium has led to the use of adequate filtration and a recognition of the significance of homogeneous distribution of radiation has resulted in the use of external radiation whenever possible and multiple implants when interstitial irradiation is indicated.

Since these principles have become recognized it is not difficult to explain many of the failures of radiation therapy under the older technique. The use of glass radon seeds, for

Plate V.

Fig. 2. Exposures of photographic films to milligram radium needles. (Plate V the needle was suspended above films which were separated by a distance of 3 millimeters. The uppermost three photographs are the first three films, reading from left to right. The lowermost three films are the films which were the farthest away from the radium needle. The film in the lowermost right hand corner was 25 millimeters away from the tip of the needle. Note the varying size of

example invariably caused necrosis on account of the absence of filtration and the frequent failures of gold implants can be explained on the basis of inadequate filtration and the difficulty of effecting a uniform distribution of radiation except in lesions of limited size.

These considerations have resulted in important changes in technique in recent years. The ideal form of radiation therapy is that which permits the delivery of an adequate uniform dose of penetrating irradiation over a prolonged but limited interval for example by the use of a large quantity of radium at a

distance. In the treatment of the more radio-resistant tumors, however the amount of radiation that can be delivered to the lesion by external radiation may be inadequate and interstitial radiation becomes necessary in order to deliver an adequate dose to the tumor. Under these circumstances the use of multiple weak radium foci adequately filtered and uniformly distributed becomes the method of choice. With a few isolated exceptions removable platinum iridium needles of 0.5 millimeter wall thickness, containing radium element have proved to be superior to

Plate B

the exposure effect upon the film. In Plate B the radium needle was placed through the films as illustrated in the diagram in Figure 1 b. Note that the exposure effect upon the films was equally as strong in the lowermost as in the uppermost film and that the extent of the radiation from the needle was uniform along its entire course.

any other method of interstitial radiation. The radium element is distributed throughout the platinum needles in such amounts that the total dose determined by clinical experience is delivered over a prolonged period of approximately 5 to 7 days. This distribution of radium permits the use of a small quantity of radium over a period of 120 to 168 hours rather than a larger quantity over a period of 10 or 12 hours. In the treatment of cancer of the tongue, for example, the use of this method has proved highly successful. Within the last few years the use of removable

platinum radium needles has been extended to the treatment of other neoplasms notably inoperable carcinoma of the breast.

Although radium implantation has been practiced in tumors of the brain and numerous studies have been made upon the effect of radium on normal brain tissue most of these observations were conducted before these basic principles were fully recognized and the radiation was not executed in accordance with the newer technique embodying these factors.

The prime purpose of these experiments was to study the effect of removable radium

Fig. 3. Brain of Cat Ra No. 6. Note the discrete wound in the cortex made by the radium needle and the absence of reaction about it.

needles upon the normal brain tissue of animals and man under conditions in which the irradiation is delivered according to the modern concepts of adequate filtration, prolonged exposure and homogeneous distribution.

EXPERIMENTS

Ten cats, 9 dogs and 1 monkey were used as the experimental animals. Platinum-iridium needles with walls 0.5 millimeter thick, 22 millimeters long, which contained 1 milligram of radium element were employed for implantation.

With two exceptions the radium needles were implanted in the parietal area of the cerebral hemisphere. In 2 cats, implantations were made into the cerebellar hemisphere. In one series, one needle containing 1 milligram of radium was implanted and left in place for 24, 48, 72, 96, 120 and 216 hours. The animals were sacrificed at the end of those pe-

riods. In another series, 4 milligrams of radium were implanted for periods of from 48 to 216 hours; the total number of milligram hours therefore were from 192 to 864. After the radium needles were removed the animals were allowed to live and were sacrificed at intervals of 20 to 168 days.

It became evident early in the course of the experiments that the animals would tolerate a larger number of radium needles provided a small amount of bone was removed and the dura mater was left open over the site of the implantations. The needles were introduced into the brain at intervals of about 1 centimeter about the circumference of a circle. The fine silk sutures attached to the eyes of the needles were placed beneath the temporal muscle. It was believed that each radium needle would exert its maximum effect at a distance of 1 centimeter and that in applying this method of therapy to intracranial tumors it would be necessary to place the needles within the tumor at 1 centimeter intervals.

In an attempt to demonstrate the limits of the area of radiation from a 1 milligram radium needle of the type used, we exposed a pack of 12 photographic films separated at intervals of 3 millimeters. The needle was suspended above the films in a darkened room for 24 hours (Fig. 1). It will be noted that the intensity of the shadow varies so that the bottom film showed no registration from the radium. Therefore the maximum radiation occurs within 1 centimeter from the tip of the needle. In another pack of 6 films, also separated by a 3 millimeter interval, the needle was inserted through the films (Fig. 2). It may be seen that along the entire length of the needle the area of radiation is of the same intensity and size.

None of the animals, regardless of the number of milligram hours of exposure and the time of sacrifice, showed any symptoms of damage to the central nervous system. It is true that the implantations were made in a relatively silent area of the cortex but it is clinical proof of the fact that the radium did not injure the brain at any great distance from the site of its implantation.

The brains were removed in every instance after formalin fixation *in situ* and there was

no operative or therapeutic mortality. Coronal sections of the brain were embedded in paraffin and in celloidin. Microscopic sections were cut at 10 millimeters to 30 millimeters in thickness and were stained by the hematoxylin-eosin Van Gieson, Cresyl violet and Weill methods. Frozen sections were made and stained by the Herzheimer, Cajal nerve fiber and gold sublimate methods, Kanzler's method for microglia, Ortega's IV, and Penfield's combined method for oligodendroglia and microglia.

The brains of two animals may be described as typical of the series in which the radium was inserted and the animals sacrificed at intervals of 24 to 216 hours. In Cat Ra No. 6 a 1 milligram needle was inserted in the left parietal cortex on December 22, 1931, and the animal was sacrificed December 28. During that interval the animal had been quite normal in every respect. The cortical vessels of the left hemisphere were a trifle more prominent than those on the right, but otherwise the appearance of the two halves of the brain was identical. The needle wound was discrete and there were no immediate gross meningeal changes about it (Fig. 3). This brain had therefore received 144 milligram hours of radiation.

Upon microscopic examination a collection of polymorphonuclear and round cells were

evident at the site of insertion of the needle and were localized to this area. The leptomeninges were slightly thickened immediately external to the needle tract but over a very limited area. The blood vessels of the left hemisphere were large and filled with blood cells. There was no apparent thickening of the endothelium of the vessels, but there was a thrombosis of many of the small vessels about the region of the needle tract. This thrombosis extended about 3 millimeters away from the border of the immediate lesion (Fig. 4). The tract of the needle was necrotic and hemorrhagic. There was no evidence of fibroblastic infiltration of the lesion but numerous gitter cells filled with fat were present (Fig. 5). The gitter cells showed evidences of migrating to the vessels in the vicinity of the needle tract though few were present in the perivascular spaces. Demyelination was distinctly limited to an area less than a millimeter distant from the needle tract. Within that zone many myelin sheaths still remained but were greatly swollen. The nerve cells in the immediate zone were slightly swollen and vacuolated. There was very little evidence of neuronophagia. At a distance of 2 millimeters from the needle tract all the architectonic structure of the cortex was normal, with the exception of thrombosed small blood vessels as has been mentioned.

Fig. 7. Photograph of Dog Ra No. 4. Four milligrams of radium have been implanted in the cortex and allowed to remain for a total irradiation of 576 hours. They were then removed. This photograph was taken on the one hundred fiftieth day. A ray plate of skull of Dog Ra No. 4 shows the radium needles in place.

The brain of Cat Ra No. 8 showed the same type of changes after 216 milligram hours of exposure. The area of demyelination was well limited about the needle tract but not as closely as in those brains with smaller exposures. In the Cresyl violet stained sections there was a complete absence of nerve cells in the zone of destruction with only a few scattered greatly swollen cells remaining with barely discernible nuclei. The cytoplasm in those cells was vacuolated and the processes were absent. The Nissl granules were absent. In the area just external to the zone of destruction the cells showed a similar appearance. The inner zone measured about 4 millimeters in width and the outer 2. There was a moderate increase of glial elements. The transition to the normal cortex occurred within 6 to 8 millimeters from the needle tract (Fig. 6).

As has been stated in a second series of animals 4 milligrams of radium were implanted for as many as 216 hours, and after the needles were removed the animals were allowed to live from 2 to 168 days. In Dog Ra No. 4 for example, four 1 milligram needles of radium were implanted and allowed to remain for a total irradiation of 576 hours and then removed. The animal was allowed to live for 150 days and remained in excellent condition throughout (Fig. 7).

In the area of the needle tract in this animal a brain there was an increase in fibrous tissue which had grown in to fill the defect. Small collagen fibers passed directly from the leptomeninges into the brain (Fig. 8). In the Well stain the destruction and demyelination of the myelin sheaths was limited sharply to the edge of the needle tract and there was no residual swelling of the myelin sheaths at the edge of the lesion (Fig. 9). The nerve cells in the region of the tract were smaller than normal so that the nucleus appeared out of proportion to the cell body. The cytoplasm of some of these cells stained darkly while in others it barely stained at all. The Nissl granules were not well defined in either type of cell. In those nerve cells with lightly stained cytoplasm the processes had broken up and were retracted while in those with a heavily stained cytoplasm the processes could be seen clearly. Neuronophagia was noted with from 4 to 8 cells about each nerve cell (Fig. 10). Astrocytes and oligodendroglia both were present but the latter predominated (Fig. 11). The glial cells which were so prominent in the brains of those animals which were sacrificed immediately upon removal of the radium, were absent except for an occasional one about a blood vessel. The microglia were not present in any greater number than is normal. These microscopic changes gradually faded away until at a distance of 1 centimeter from the needle tract the normal architectonic structure of the brain was present.

SUMMARY

In summary then the pathological changes consisted of a central zone of destruction immediately in the tract of the needle wound.

Fig. 8.

sheaths which was limited sharply to the edge of the needle tract. (Weil stain)

Fig. 10. Photomicrograph showing neuronophagia with 4 to 8 cells in Dog Ra No 4. These changes occurred within 4 millimeters of the needle tract (Cresyl violet stain)

In the brains of those animals killed at the end of the period of exposure gutter cells loaded with fat thickening of the blood vessel endothelium with thrombosis of smaller vessels, amyelinization and slight chromatolytic changes in the nerve cells were the prominent features. In the brains of those animals in which some reparative processes had time to occur the gutter cells had disappeared, astrocytes and oligodendroglia cells were present in large numbers and neuronophagia was present. The important fact to be recognized is that all of these pathological changes gradually faded away to the normal within the radius of a centimeter from the central zone of destruction

CLINICAL EXPERIENCES

Thus far our clinical experience in the use of radium needles implanted within the brain is limited to one case and therefore this portion of our work is in the nature of a preliminary report

Our primary object was to determine first of all whether or not the use of radium element implanted in the brain according to the technique we have described would produce damage to the surrounding normal brain

structure. When it appeared that irreparable damage did not occur we felt justified in using it in an intracranial glioma. We believe that the case herewith reported was a severe test of the practicability of its use and that its future employment in these extensive gliomata should not be discouraged by the final result in this patient

Headaches vomiting mental changes convulsive seizures of 8 weeks duration—cribriform glioblastoma of left temporal lobe—osteoplastic craniotomy—implantation of eight 2 milligram radium needles—3,688 milligram hours exposure—death 2 months later

W. M. aged 14 years Michael Reese Hospital B48570

In February of 1932 the patient began to complain of severe headaches accompanied by vomiting. His memory was very poor and his mother stated that he acted queerly and became very difficult to manage. When he attempted to walk he became very unsteady and often fell to the floor unconscious. He would become rigid and then would have generalized clonic movements accompanied by incontinence.

Examination The skull was large but there was no tympanic note upon percussion. The left pupil was larger than the right and did not react to light. The right palpebral fissure was wider than the left. There was a high grade bilateral papilloedema with retinal hemorrhages. The right side of the face was weaker than the left and there was marked weakness in the right upper extremity. There was a pro-

Fig. 1. left. Photomicrograph to show predominance of astrocytes immediately about the needle tract. (Cajal gold stain)

Fig. 12. Photomicrograph of tumor removed from patient. This is a glioblastoma.

nounced ptosis of the left upper eyelid with difficulty in moving the left eyeball to the midline. There were no sensory changes. The boy had no aphasia, apraxia, or astereognosis. His visual fields could not be determined accurately because of his mental instability. His attention could not be held and his emotional outbursts were frequent.

Operation. It was many weeks before an operative permit could be obtained from his parents. On April 8, 1932, a left osteoplastic craniotomy was performed. The child had become stuporous and had to be fed artificially.

One and one-half centimeters below the surface of the temporal lobe near its anterior pole, a large, soft, gelatinous reddish yellow tumor mass was found. In areas it was firm but for the most part the tumor was quite soft and jelly like. The cortical cap was removed with an electro-surgical unit and a portion of the tumor was removed by a curette and a sucker. Microscopically it was a glioblastoma (Fig. 12).

Eight 2 milligram radium needles were implanted into the tumor mass at intervals of about 1 centimeter. The dura mater was left open over the temporal lobe and the bone flap was removed (Fig. 13).

Course. The immediate postoperative condition was precarious but after 12 hours his blood pressure rose to 90/50 and he was taking fluids by mouth. His temperature was 103.6 rectally and his pulse 150. Edema of the left eye and face began. He talked and moved his right arm and leg as well as he had previously. Within 24 hours the edema of his face had increased but he was more alert and his blood pressure was 128/78, pulse, 120 and temperature 98.4. His recovery then progressed rapidly so that within 48 hours after operation the edema had disappeared entirely.

Operation. On April 15, 1932, after he had received 2,553 milligram hours of radium exposure the flap was elevated and the radium removed.

Course. The patient's recovery was excellent. The wound healed well, except for a slight necrosis of its anterior limb, which eventually disappeared (Fig. 14). His mentality became greatly improved and he was allowed to be about his ward untried.

Six weeks after the removal of the radium his hair began to disappear and he became bald over the left side of his scalp.

On June 2 the patient became drowsy and hypertonic intravenous solutions did not produce any change in his condition. He gradually failed and died on June 12, 1932.

At the outset it was quite apparent that we were dealing with an extensive lesion which had grown rapidly toward the midline, as well as into the frontal lobe. He became somnolent and unresponsive—a state from which he could not be aroused by hypertonic solutions. Although the final result may have been so different, it was not until his parents saw him in this moribund state that they consented to operation.

The postoperative edema about this boy's face and left eye was more marked than we have ever seen following a craniotomy. It did not include the scalp over the bone flap and we are inclined to believe that it was due to an unusual circulatory stasis rather than to

Fig. 13. X ray plates of skull to show position of eight 2 milligram radium needles implanted into the tumor of the patient. Small silver clips are to be seen on the blood vessels of the cortex

any direct effect from the radium. He did not have an unusual postoperative rise in intracranial tension which might have been due to oedema produced by the radium. Disappearance of the hair over the left side of the scalp was a late effect which was expected. The area of depilated scalp was considerably larger than the circumference of the area in which the needles were implanted.

We have no way of knowing accurately the duration and exact time of onset of the symptoms in this patient because of the inaccuracy of the history. The microscopic picture of the tumor which was classified as a glioblastoma led us to believe that the prognosis following operation would be unfavorable since it is known that the clinical course of the glioblastomata is shorter than other tumors of the glioma group. These large succulent tumors produce tremendous oedema and intracranial tension. They grow rapidly often extending throughout both cerebral hemispheres. They have been proved to be little influenced by X ray therapy or by radical surgical operative procedures.

It is more than unfortunate that an autopsy permit was not granted because it leaves unanswered the important questions of the exact extent of the tumor and the effect of the radium upon the remaining tumor tissue and the

surrounding normal brain. These are matters for future study.

We may be certain however that the implantation of radium needles and their subsequent removal is a practical procedure the success of which may be influenced by the care which is taken in the closure of the craniotomy wound.

DISCUSSION

The direct effect of radium upon tumor tissue has been investigated many times and though we wish to record our observations

Fig. 14. Photograph of patient 14 days after removal of radium needles.

upon this point as our experience increases it is not the primary point with which we are now concerned. Our aims were to establish whether or not radium could be placed within the brain for long periods without a fatality to the patient and without serious damage to the surrounding brain structure. Our experimental evidence and meager clinical experience would lead us to believe that radium implantation into the brain in small doses, properly filtered and left for many hours is tolerated extremely well by animals and by man. This is particularly true if an adequate decompression is made to provide for any possible rise in intracranial tension.

Though a destruction of brain tissue occurred about the margins of an intracranial tumor we would sacrifice it gladly for the advantages of treating such a tumor more adequately than we are able to do at present. However we believe that such a destruction of cerebral tissue does not occur certainly not beyond a radius of 1 centimeter. This means, therefore, that we believe that many of the pathological findings we have described may have been due alone to the introduction of a blunt needle into the brain. It has been shown by Penfield (17) that about the track of a blunt needle, compound granular corpuscles occur in larger numbers, that the astrocytes send in large expansions concentrically and in general a cicatrix results which contains connective tissue and causes gliosis and a distortion of the brain. Our results, therefore, are in accord with those of earlier investigators in that they show that radium in the doses which have been used does not materially injure normal brain tissue.

The tendency for radium and X ray therapy to increase the capillary supply of the area treated was a question which arose during the investigation. We concluded that the pial vessels of the cortex were not increased in size or number and that we could discount the possibility of the development of a telangiectasis. Finally there was no microscopic evidence of an increased vascularity nor was there in any instance a tendency for secondary hemorrhage to occur.

In none of the animals and in the single clinical experience there was no disturbance

of the heat regulation mechanism. Though the needles were in many instances close to the ventricular walls, there was no destruction of the wall and no ventricular hemorrhages occurred.

It must be remembered that some of the gliomata have a more embryonic structure than others, further that the clinical course of some of them is longer before and after operation than others. The general experience of neurological surgeons with deep roentgen-ray therapy is in accordance with these two facts, though an exact law of behavior of the tumors to radiation is not possible. We have no doubt that such may prove to be the case with the use of radium. It is unlikely that the astrocytomata or oligodendrogliomata which have a relatively slow clinical course will be affected greatly. However it is the outlying and peripheral extensions of these tumors which are in more active cellular division which we wish to inactivate by the implantation of radium needles. It is probable that a much larger initial dosage will be required for the glioblastoma group, an example of which we have reported upon.

CONCLUSIONS

1. The ideal form of radium therapy by implantation of needles is that which makes use of multiple weak radium foci adequately filtered and uniformly distributed over a period of 120 to 168 hours.
2. Radium element implanted into the brains of animals under such conditions produces no destruction of normal brain tissue.
3. It is surgically practicable to implant radium needles in a brain tumor and remove them after the period of radiation.

We wish to express our thanks to Mr. L. H. Terrell for his help in preparing the microscopic sections.

SOME PRINCIPLES INVOLVED IN THE PATHOLOGY AND TREATMENT OF EMPYEMA THORACIS

WITH PARTICULAR REFERENCE TO TREATMENT BY PERIODIC ASPIRATION OR EVACUATION WITH AIR REPLACEMENT WITHOUT DRAINAGE¹

JOSEPH A. DANNA, M.D. Ph.D. F.A.C.S., NEW ORLEANS, LOUISIANA

Professor of Surgery, Graduate School of Medicine, Louisiana State University Medical Center; Senior Surgeon, Hotel Dieu; Senior Surgeon, Charity Hospital

THE pathology of empyema differs in only one respect from the pathology of infection of the peritoneum or any other endothelial cavity namely in that pus forms in an area in which negative pressure exists. Whereas, in the abdomen a simple incision into the cavity and sufficient drainage to permit all the products of the suppurative process to escape are usually sufficient for the establishment of a cure in empyema the presence of negative pressure complicates the mechanism of healing the cavity having a tendency to pull apart and stay open rather than to collapse.

The pleural cavity may be infected in one of three ways

1 By the direct introduction of contaminated material through a wound including an operative wound

2 Through the blood stream This is very rare for even when blood stream infection does occur it usually involves infection of the subjacent tissues before the endothelial lining itself is infected so it is not a direct blood stream infection of the pleural cavity

3 By the spread of infection from an adjacent organ or tissue This is the usual mode of infection and may occur first by the spread as in pneumonia or influenza of an inflammatory process from the lung substance onto the endothelial surface second by the rupture of a cortical abscess of the lung which may either be so minute as hardly to leave any signs detectable at autopsy or it may be so large that the sudden pouring of its toxic contents into the pleura, especially if no adhesions exist may cause profound shock and even perhaps death before any surgical procedure can be instituted. There may be any grade of severity between these two extremes. Again, the pleura may be infected by the rupture of a subphrenic or liver abscess through the

diaphragm of a chest wall abscess through the parietal pleura, an oesophageal lesion through the mediastinal pleura by the rupture or spread of a suppurative process in osteomyelitis of the ribs, of a similar lesion of a vertebra or by the spread of infection from a purulent pericarditis

A single pocket of pus will form if the focus of infection is a single one the inflammatory process a slow one the bacterial infection not highly virulent and if it is situated in an area where there is little motion as in the upper portion of the chest, in an interlobar space or in the immediate neighborhood of an adherent area. These conditions permit sufficient time to elapse for the formation of adhesions. This pocket will be small at first, containing little fibrin. It will grow gradually in size and if not incised or drained or otherwise emptied will finally overcome the cohesive force of fresh adhesions and rupture into and involve the entire pleural cavity giving rise to symptoms of shock and toxemia as in the rupture of a lung abscess. Where, however the surrounding adhesions are very firm, a rupture may take place through the lung parenchyma into a bronchus and be drained partially in this way. More rarely it may break through the parietal pleura into the tissues of the chest wall and finally point on the surface or similarly invade the pericardium or subphrenic area.

If the focus is situated in an area where the lung moves widely and freely or if there are a number of scattered small foci, or infected material is poured rapidly or in any great quantity into the pleural cavity and if the infecting organism be of a highly virulent type giving no time for the formation of protective adhesions then the entire pleural cavity on that side will become involved as one large abscess cavity. This is the type usually

FIGS. 1 and 2 Drainage tubes of different variety in place and cavity in each case entirely empty of pus and filled with air

seen as a complication of influenzal pneumonia. As the purulent fluid increases in quantity the lung gradually collapses and finally the heart and mediastinum may be pushed over toward the unaffected side. These large cavities may contain large masses of fibrin both adherent to the walls and floating in the fluid.

If a cortical abscess no matter how small communicating with a bronchus should rupture into the free pleural cavity a bronchial fistula will result. Reinfection of the cavity will continue till the fistula closes and air may be forced into the cavity at each effort at coughing or straining adding a spontaneous pneumothorax to the empyema the combination being known as pyopneumothorax. This latter condition occurs more frequently in children and following gunshot or stab wounds of the lung in adults. It presents the added danger of a possible tension pneumothorax which, especially in children may increase to the point of pushing the heart and mediastinum over so far as not only to diminish the actual breathing capacity to a point dangerous to life, but also to interfere with the circulation by pressure on the venae

cavae and innominate veins, thereby preventing the ready filling of the right heart. This danger is to be constantly remembered in treating empyema by any truly closed method.

No matter what treatment is instituted the empyema will persist and pus continue to re-

Figs. 4, 5, 6, and 7. Various steps in air absorption and lung expansion in a patient treated by aspiration and air replacement. Figure 4 shows practically the same con-

dition as Figure 3. Note the diminution of density of the lung in Figures 5 and 6 as air is absorbed and the lung expands.

form until the source or focus of infection has ceased to pour infected material as it were into the pleural cavity. Thus bronchial fistulae and communications with a lung cavity or with any other infected area must close before the suppurative process can stop. Long continued bronchial fistula, or other persistent sinus opening into the empyema cavity is the most frequent cause of chronic empyema.

As brought out by Graham (9) a large empyemic accumulation involving more or less of the entire hemithorax even with virulent organisms may not very materially immediately endanger the patient's life if both lungs are otherwise comparatively normal.

But in the presence of any pathology which curtails the function of either lung and especially of the lung on the opposite side par-

ticularly if associated with the usual additional toxemia and exhaustion of a patient who is very sick from an acute pneumonic condition then even a very small empyemic accumulation may prove to be a very serious complication. Thus in pneumococcal empyema which develops after the subsidence of the acute pneumonic process, the condition is not nearly so serious as in influenzal empyema which usually develops during the progress of the acute influenzal process in the lung. The virulence of the bacteria present also influences the severity of the case.

HEALING OF THE EMPYEMA CAVITY

How does an empyema cavity heal? A *small* cavity may perhaps heal by granulation and cicatricial approximation of the separated pleural surfaces. It is difficult to conceive, however, that a cavity as large as half the chest cavity could possibly heal in this way. *Large* cavities diminish in size only to a very limited extent as a result of granulation and cicatrization. The main mechanism of healing after reinfection has ceased is by

1. Sealing of the cavity from the outside, resulting in a closed pneumothorax,

2. Gradual absorption of the remaining air, the lung being drawn out by the resulting increase in negative pressure until all air has finally been absorbed, when the cavity is obliterated.

In these larger sized cavities when all pus and all dead material including fibrin clots, necrotic tissue etc. have been removed or drained out, and the cavity ceases to be reinfected from within or without, pus practically ceases to re-form. So far as the walls of the cavity are concerned the condition is now analogous to the clean granulating surface of an abscess after all necrotic material has been cleared out. This is equally true whether drainage has been used or the contents have been removed by needle or otherwise. At this stage the infecting bacteria no longer float in a lake of pus which is a most favorable culture medium but lie in contact with and hence at the mercy of the activated fixed tissue cells which now amply care for what contact bacterial infection is left on its surface. Thus the cavity becomes practically

sterile soon after it is freed of all fluid and dead and extraneous material. The ability of an endothelial surface to care for a certain amount of bacterial contact infection is familiar to laboratory workers, who find it difficult to infect an endothelial cavity. Graham (8) found it very difficult to produce empyema in experimental animals by introducing even large quantities of bacterial laboratory cultures. The abdominal surgeon does not fear peritoneal contact with infected material if no gross fluid or solid matter remains and usually feels safe if he can wipe the contaminated surface clean.

To get back to our subject, we now have a clean cavity filled with air. The drainage tube, if any, may at this stage be surrounded by granulations and adhesions which shut it off from the cavity. In any event it traverses an area of greater or lesser depth of clean healthy granulations which will readily come together with rapid closure of the drainage sinus if the tube is now removed. Bacterial counts in smears taken from the wound are a valuable aid in determining the optimum moment for removal of the tube, though one can usually judge by the quantity and quality of drainage. A roentgenogram taken at this time will show a pneumothorax cavity of approximately the size of the original empyema cavity (Figs. 1, 2, 3). Identically the same picture is shown when aspiration and air replacement has been used (Fig. 4). The cavity now, sealed from the outside, gradually diminishes in size as the contained air is gradually absorbed, and is finally completely obliterated, as can be shown by repeated roentgenograms (Figs. 4, 5, 6, 7).

The impression seems to be general that these cavities fill from the bottom, as evidenced by the fact that the cavity will hold less and less irrigating fluid. Whatever may be the explanation of this phenomenon, the fact remains that it cannot be generally so, for if frequent roentgenograms are taken, no filling in of the cavity by granulations is evident and comparatively little diminution in the size of the cavity in the drainage cases takes place until the drainage sinus closes. After this the lung can be seen gradually expanding and approaching the chest wall.

During this process its shadow becomes not denser as it would if to the lung shadow were added the shadow of superimposed new granulations, but less dense owing to thinning of the lung substance as a result of its expansion and filling with air from within.

Some granulation and cicatrization does occur however not only around the tube but also in the angles of the cavity so that the cavity in this way grows somewhat smaller. If the process is of long standing continued inflammatory infiltration renders the lung surface more and more hard and unyielding its edges become firmly bound to the chest wall diaphragm or mediastinum, and there results the type of chronic empyema which is due to inability of the lung to expand as the air is absorbed.

In every case when healing has taken place and all air has been absorbed, the pleural surfaces are finally glued together over a greater or less area by firm organized adhesions. Where tube drainage has been used the adhesions are more pronounced and cover a larger area. In fact the opinion prevails that in all cases the entire surface involved becomes permanently adherent. An experience with two patients with pyarthrosis of the knee who were treated by aspiration and air replacement and who are well with practically no impairment of movement, makes me lean very strongly to the opinion of Forlanini that it may be possible. If little trauma is inflicted on the pleura by treatment to have the endothelial surfaces at least over a greater or less area finally free of adhesions. We know that this is so in the peritoneal cavity. True the frequency with which pleural adhesions are encountered at autopsy in patients never known to have had any such serious pathology as empyema may be cited as evidence that things are different in the pleura. But the question will bear consideration and investigation. I believe it not only possible but probable that in many cases treated by aspiration and air replacement, during the period of 2 or 3 weeks or more required for complete air absorption that follows clinical cure, the endothelial surfaces may revert to normal and glide freely over each other when they do come in contact.

I may say a word at this point as to the use of antiseptic washings. There should be no more need or indication for them here than in the peritoneal cavity or elsewhere. Most other abscesses do better without antiseptic washes or interference of any kind. Against this, however stands out the remarkable improvement and shortening of convalescence which followed the introduction of irrigation with Dakin's solution during the World War. This irrigation is still very popular and quite generally used. The solution it is said will cause the fibrous masses to dissolve and drain out. If this is desired I wonder if papain (1:10) or some other digestant would not be more effective.

That the fibrin will liquefy is attested by the many cases of empyema that have during these recent years gotten well by the use of small catheter drainage and by some form of aspiration, in the greater number of which no irrigation has been used. For as experience with rib resection and open tube drainage has taught most patients have fibrinous masses that could not pass through a needle or small catheter. These masses, therefore must have been reduced to a state in which they would pass through a small catheter or aspirating needle.

DIAGNOSIS

The early diagnosis of empyema is not always easy. In cases in which a known hemothorax or marked serous effusion is infected and becomes purulent this may be readily determined by exploratory puncture. This is not however the usual way in which the largest number of empyema cases in civil practice begin. They usually start as a small intrapleural accumulation temporarily walled off by adhesions. This may be situated in any region of the chest cavity. If treatment is instituted in this early stage one has to deal with only a small accumulation. If the case however is not recognized early and no active treatment has been instituted the adhesions are finally overcome and more or less of the entire pleural cavity will be involved. The localization of a small accumulation is often very difficult. If deeply situated physical examination may reveal nothing abnormal. If near the surface there will be dullness and

diminished or even absent breath and voice sounds. Next to the finding of pus by needle puncture, roentgenography is the most valuable single means of diagnosis. It has however all the possibilities of error inherent in the interpretation of shadows. When pus is found, the localization and outline of the cavity may be very much facilitated by removing as much pus as possible even though in small quantity and replacing this pus with air. Roentgenograms now taken with the patient in a number of different positions and with the rays directed *horizontally* will show a fluid line with air above so that it is possible by a study of a series of views to outline definitely the entire cavity. If the cavity has been completely emptied of fluid with air replacement, it will stand out clearly in the roentgenogram in any one position.

One should never be satisfied that pus is not present because of a single negative exploratory puncture and the largest possible needle should be used for very thick pus will not flow through the usual aspirating needle. There may be two or more separate noncommunicating cavities each of which will require separate treatment. A small empyema pocket may be situated deeply in an interlobar area, or over the dome of the diaphragm or between the lung and pericardium or mediastinum so that healthy pleura or lung must be traversed in order to reach it. In such cases the course is to all intents and purposes like that in a lung abscess. In their drainage, open or closed one may cause infection of the general pleura or injury to the lung substance. It is sometimes very difficult to distinguish between an abscess and an empyema cavity. Here one's clinical sense must come to his aid. A patient with a lung abscess is usually much more seriously ill than one with an empyema cavity of equal size. If the abscess is cortical and adhesions exist, there is usually no serious danger in inserting a needle into it. One will meet, however, the occasional foul smelling anaerobic lung abscess, the puncture of which may result in an acute phlegmonous infection of the chest wall with the most serious consequences.

I have said nothing about pathognomonic physical signs of fluid in the chest. Areas of

dullness in empyema do not change with position as has been taught, even in large effusions, unless a considerable quantity of air is present, for the structures which surround an empyema cavity very early become fixed so that the lung cannot shift position in different postures.

PROPHYLAXIS

Can we do anything to prevent empyema? Children with whooping cough or other pulmonary conditions who have violent repeated spells of coughing should be given such remedies as will minimize the violence of the efforts at coughing and thus avoid, if possible the rupture of a cortical lesion and the production of spontaneous pneumothorax which may occur even without any lung pathology. Chest wall infections should be incised early. The same is true of liver and subphrenic infections. In making an exploratory puncture or in aspirating a serous effusion one should observe every aseptic precaution so as not to convert a serous into a purulent effusion. All effusions should be evacuated. Especially is this true of hemothorax. The chest should be emptied of blood just as soon as sufficient time has elapsed to make one reasonably sure that the hemorrhage will not recur. If the blood or serum is replaced with air, every drop of fluid can be withdrawn without altering the intrapleural tension. In fact, as brought out by Morelli, to prevent recurrence of hemorrhage or even to arrest it if persistent, a larger amount of air may be injected than the fluid removed, to the point of producing positive pressure if necessary. As the air during the ensuing 2 or 3 weeks is gradually absorbed the lung will gradually expand. Patients with chest lesions, whether inflammatory or traumatic, should be the object of solicitous care and should be frequently visited and examined by the physician or surgeon and frequent roentgenograms should be taken.

TREATMENT

Three methods of treatment of empyema are now in vogue. First, incision and open drainage with or without rib resection and with or without irrigation of the cavity. A

large rubber tube is the most generally used means of drainage. Some go so far as to advocate gauze packing of the entire cavity (2). Second closed tube drainage, a large catheter or similar tube being inserted through a small stab wound or by means of a trocar the tube being intended to fit so tightly that there is no leakage between it and the surrounding chest wall. Some form of suction more or less continuous, and some form of irrigation is the rule. Third aspiration.

I shall also discuss a fourth—periodic aspiration or evacuation of the pus with air replacement and without drainage.

Incision with or without rib resection and open drainage. This was the method generally in use until the outbreak of the World War. During the measles and influenza epidemics, the reports from the various Army hospitals in the United States to the Surgeon General's office showed the death rate from empyema after open operation to average 30 per cent in some hospitals and in others to run as high as 70 per cent. The Empyema Commission (20) found the highest mortality in the hospitals in which open drainage was instituted as soon as an effusion became purulent or pus was located. Everts A. Graham (9) a member of the Commission carried out experiments showing the manner in which a large opening in the chest wall endangered life the danger being proportionate to the size of the opening. He showed that in the prevalent type of streptococcal infection, the empyema developed while the lung condition was at its height, and not after its subsidence as in the pneumococcal type. He also showed that open thoracotomy could be done with a greater margin of safety later when the mediastinum became rigid as a result of inflammatory infiltration so that the disturbance of equilibrium incident to operation could not be transmitted to the lung and pleura of the other side.

The result was deferred operation. Temporary aspiration was done as indicated and some patients were cured by this aspiration alone. When operation was done later, openings only large enough to insert a tube were made and even the tube was protected by dressings or some special valve-effect appliance and its caliber diminished by smaller

tubes inserted for irrigation with Dakin's solution. This solution seemed to sterilize the cavity dissolve the fibrous masses, and shorten the period of convalescence. Repeated wound cultures were taken and when the secretions were sterile or the bacterial count in smears from the wound reached a very low figure, the tube was removed. Treatment was more or less standardized along these lines, and a marked reduction in the mortality rate resulted.

As compared with other methods, open drainage has the following advantages (1) The surgeon has the satisfaction of looking into the cavity or removing a few large fibrous flakes and even of putting his finger into the recesses of the cavity. (2) In most instances, unless there is later delay in healing, the surgeon is through with his work when the operation is finished and the patient has rallied from any resulting shock. No close, repeated personal observation is required on his part if convalescence is normal. In a large number of cases the patient may get well without his having seen him again, ample care being given him by the nurse. (3) Irrigation can be done if desired. (4) Tension pneumothorax is impossible. (5) Foreign bodies can be removed.

On the other hand (1) there is always shock of varying degree, depending upon the degree of rigidity of the mediastinum, the amount of lung disease present, and the care used in minimizing the effects of open pneumothorax by hand or gauze closure of the wound during the operative procedure, valvular closure of drainage tube, etc. (2) There is much secretion and drainage, requiring frequent abundant dressings, the patient being more or less constantly soaked in fetid pus and therefore a nuisance to those about him. (3) The tube may not be placed so as readily to drain the cavity and a second thoracotomy may be required. In this connection, many surgical textbooks describe the exact spot on the chest wall at which a thoracotomy should be done. I heard a very able surgeon who holds a high hospital and teaching position recently say he always resects the sixth rib in the posterior axillary line. Those who practice such a set rule will strike an empyema

cavity in most instances, if the entire pleura is involved. I should have missed it in nearly half of my own series of cases. Evidently, these men very seldom see empyema in the early stages. Or do they drain at one spot and then find their way to the cavity by dissection, or separation of adhesions? (4) Occasionally a tube gets lost in the cavity with resultant embarrassment for the surgeon and trouble for the patient. (5) As a result of the presence of the tube (a) some secondary infection is inevitable (b) pressure contact may result in intercostal hemorrhage ulceration into a bronchus, rough granulation about the tube, and if long continued the formation of a thick walled sinus with greater tendency to chronic empyema than by any other method. (6) There is always a deforming scar.

Closed drainage. As early as 1890 Forlanini reported 6 cases of empyema treated in the previous 2 years by this method. He recites a controversy at the Medical Congress in Vienna in 1889 between the advocates of wide open incision and drainage and the partisans of what he called the Bulau method which is exactly the closed tube method as practiced today. He favored the latter but said that complete emptying of the cavity was essential to a cure and the Bulau method did not remove all fluid at once. The fluid could only be removed by replacing it with air. He, therefore, by needle puncture or after introducing a Nélaton catheter through a trocar removed all fluid by repeated alternate suction of fluid and injection of air. He produced a negative pressure in the cavity by replacing the fluid with approximately one half its volume of air. This negative pressure he maintained by a sealed two-bottle gravity method. He aimed at keeping the cavity free of pus and favoring closure of the cavity by constant suction. He also used repeated washings of the cavity mostly with boric acid solution. This, except for the complete emptying by air replacement describes the present day method. In fact there is much talk to the contrary of keeping air from entering so as to prevent pneumothorax. This is a misconception of the principle of avoiding a marked open pneumothorax which means a free opening which allows air easily alternately to

enter and escape with each respiratory cycle. Forlanini's article would well repay reading by any one interested in this subject, for there is hardly any aspect of the pathology and treatment of empyema that he does not discuss, many of his terms being in the language of what is considered most up-to-date on the subject today. Morelli, Forlanini's pupil and successor, does a rib resection, inserts into the pleural cavity a large tube which traverses an hourglass inflatable balloon intended to give an air tight fit, irrigates with chloroform, and maintains negative pressure (Fig 12). This technique gave him excellent results in the treatment of fresh thoracic wounds.

Closed small tube drainage can be instituted without the shock incident to open drainage and without the dangers incident to an open pneumothorax. Irrigation of the cavity can be done if desired. Negative pressure can be maintained by some form of suction, this being by many considered desirable, as favoring earlier collapse of the cavity. Others encourage collapse by forceful blowing exercises against resistance. Forlanini used inhalation of air under pressure. I believe little is to be accomplished by any of these measures except in so far as they help to empty the cavity of pus. To the contrary, they may all have a tendency to favor the passage of fluid exudates from the lung into the cavity and to maintain or re-establish the patency of a bronchial fistula or infecting sinus.

As disadvantages of the method may be mentioned (1) The small tube may be blocked by plugs of fibrin, (2) it may not completely drain the cavity, (3) the tube may not remain air tight, air finally finding its way between it and the surrounding soft parts, favoring secondary infection, (4) to a lesser extent than in open tube drainage, granulations form about the tube and chronic empyema may ensue if drainage is of long duration. (5) possibility of tension pneumothorax.

Aspiration. As Forlanini well brought out, it is impossible to empty most empyema cavities completely of all fluid by aspiration alone. In fact, he divides them into three classes according to the degree to which the walls yield to suction (1) in which the walls yield

Fig. 8. Making small stab wound to facilitate introduction of large needle.

readily to aspiration (2) in which the walls yield later to continued suction (3) in which they never yield and thoracoplasty has to be done to collapse the cavity.

The accidental or incidental cure of empyema by aspiration is as old as aspiration itself. During the World War experience more than 10 per cent of the cases were cured by the aspiration which was done as preliminary to later thoracotomy. But no one has ever definitely shown that any great number of consecutive cases can be cured by aspiration alone. Nor have I ever made such a claim. It may occasionally be possible to remove most of the pus in an empyema cavity by simple aspiration. I think however that this rarely takes place. What often happens is that during the course of the aspiration air is permitted in some way to enter the cavity and that these cases are really being treated not by aspiration alone but by aspiration and air replacement.

Air may find its way into the cavity (1) by suction through the needle while disconnected from the syringe (2) by needle puncture of the lung, (3) by tearing of the lung by the force of aspiration. I recently discussed a paper (13) by an eminent pediatrician on aspiration in the treatment of empyema who stated that he had had no experience with aspiration and air replacement. I was able to show by one of his own lantern slides that

Fig. 9. Large needle attached to clamped rubber tubing and ready for connection to syringe. (First method of aspiration and air replacement.)

he had if accidentally and unknown to him practiced air replacement for he showed a cavity completely filled with air and completely empty of pus after one of his aspirations. Instances are on record (17-19) where the pull of forceful aspiration tore the lung substance producing a bronchial fistula and spontaneous pneumothorax and permitting free emptying of a cavity after previous repeated negative attempts. McEneary and Brennemann describe the incidence of pyopneumothorax after one or more aspirations and frankly attribute it to pulmonary trauma by the aspirating needle. They also cite an instance where a hypodermic needle used to give a cardiac injection of epinephrine perforated the thin leaf of left lung overlapping the heart, producing marked pneumothorax and when at autopsy the lung was inflated through the trachea, air bubbled out through the opening made by the small needle.

Periodic aspiration or evacuation with air replacement without drainage. Forlanini's article, already cited describes a method of emptying completely the chest of fluid by aspiration and air replacement. He gives Parker credit for first suggesting it. This same method was described and credit given to

Fig 10. Large needle connected to suction apparatus and smaller needle inserted higher up connected to pneumothorax apparatus, both controlled by forceps clamping. Glass tubing connection in lower tube near the needle end of the tube through which air bubbles can be watched for to determine when the cavity is empty of fluid. (Second method.)

Forlanini by Morelli, his pupil and successor in a monograph on wounds of the chest in 1918. While serving with U S Army base Hospital No. 102 on the Italian front a short distance from Morelli's Special Hospital for thoracic wounds I became acquainted with this method through the same monograph and for a number of years after had occasion to use it in the removal of non purulent effusions.

If one tries to empty the chest of a fluid accumulation by simple aspiration with no air replacement one eventually has to stop without removing all the fluid for one of two reasons either the negative pressure becomes so great as to cause pain and respiratory or cardiac embarrassment or the needle will come in contact with the visceral pleura and cause pain, coughing, dyspnea and shock. If, instead, the fluid is gradually replaced with air as it is removed, the cavity maintains its original size and shape, and every drop of the fluid can be removed with practically no discomfort.

It did not occur to me to use this method in the treatment of empyema until 1923, when I had occasion to perform a temporary aspiration on a young woman with an empyema complicating an influenzal pneumonia. Hav-

Fig 11. Graphic demonstration of third method showing long forceps introduced through small stab wound permitting free flow of fluid outward and air inward and ready to grasp fibrinous masses that may present in wound

ing found pus by exploratory puncture, I decided while the needle was still in place to remove as much pus as I could previous experience with aspiration with air replacement of non purulent effusions encouraging me in the belief that I should be able to do this without harm or discomfort to her. This I proceeded to do, easily removing 300 cubic centimeters of frank pus and replacing it with an equal volume of air. The patient improved remarkably immediately after this, and when a few days later I spoke of thoracotomy she suggested another aspiration which I did again replacing the fluid with air, and finally did the same thing a third time. Following this the patient was clinically well and has been well since. Thus my initial case was accidental and unexpected.

Two years ago I reviewed (3) 35 consecutive cases treated by this method. I have had a few more since, and know of some 75 more treated by others in New Orleans and elsewhere. The patients have been of all ages, varying from a few months to 75 years, and of practically every variety of etiology and bacterial infection. I myself have had but 2 deaths, neither of which I believe was attributable to the treatment. I feel more and more with increasing experience that the method has much merit, and while it has its weak points and even its dangers, yet I believe it is applicable as generally as any other one method and especially so in very sick patients. So that judiciously used it should

Fig. 12. Inflatable bougie balloon of Morelli traversed by large drainage tube. Note smaller tube for inflation of balloon. These bougie balloons are made in different sizes and inflated sufficiently to give an airtight fit without undue compression of tissue. The balloon and tube are removable, a smaller one being used as the opening gets smaller.

lower the mortality of any one doing a large volume of this work.

I should like to see it more generally used and especially advise the most skeptical to use it as a preliminary measure to their own pet method. Many I am sure will be surprised by the results.

It may be interesting here to remark that Forlanini tried to treat his first two cases by aspiration without result. He later used aspiration with air replacement, getting complete emptying of the cavity and these first two cases were cured by this method. In the remaining cases he used it only as a preliminary measure followed by closed tube drainage and in his concluding remarks says that one should not lose time trying aspiration. I must also say that I was not familiar with these facts nor with the work of Elias until I looked up the literature in December 1930 in the preparation of my paper published in 1931 (3).

TECHNIQUE

Three methods are used to remove the contents of the empyema cavity and replace it with air.

1. In small effusions by puncture with a single large needle attached to a syringe.

2. In large effusions by puncture with a large and a small needle to which a suction apparatus and a pneumothorax apparatus are respectively attached.

3. Where the needles become blocked by temporary small intercostal incision with emptying of cavity by repeated forced inspiratory and expiratory effort.

In small effusions. The site and outline of the purulent effusion having been determined a point in the intercostal space corresponding to the lowest point of the empyema cavity is anesthetized with 0.5 or 1 per cent solution of procaine hydrochloride all the tissues from skin to pleura inclusive, being thoroughly infiltrated. A large needle is now attached by a stiff rubber tube connection to a 50 cubic centimeter Luer syringe and inserted at this point. A syringeful of pus is now aspirated the tube is clamped with hemostatic forceps, the syringe is disconnected, emptied, filled with an equal quantity of air and reconnected to the tube and needle the forceps are unclamped and the contained air is injected. This alternate aspiration of fluid and injection of air is repeated until, on aspiration air comes through the needle which shows that the needle point is now above the fluid line or that all fluid has been aspirated. The patient and needle are manipulated so as to make sure that the needle point rests in the bottom of the pus cavity and the procedure is repeated until air again comes from the needle, which indicates that no more fluid remains. This is preferably done with the patient sitting up, but very sick patients are treated lying down with the head and shoulders slightly elevated. It is essential that the connecting rubber tubing be very stiff as ordinary tubing will collapse with the amount of suction usually required when the pus is thick. The introduction of a large needle is much facilitated by making a small skin stab with a sharp pointed knife (Fig. 8). The needle attached to the clamped tubing may more conveniently be inserted before connecting with the syringe. (Fig. 9).

In large effusions. A second spot in the chest wall is infiltrated with the anesthetic solution and a second smaller needle is introduced. The first larger needle is connected to the suction apparatus and the second needle to some form of pneumothorax apparatus whereby the amount of air that comes through can be measured and the cavity rapidly emptied by simultaneous suction and air injection (Fig. 10).

When the aspirating needles are blocked in some cases the fibrinous exudate prevents

complete emptying of the cavity by hocking even the largest needle, rendering it possible to aspirate, at most, only from one half to two-thirds of the contained pus. If delay is inadvisable, a small intercostal incision is made, just large enough to introduce the index finger, the patient is turned so that this incision lies at the most dependent part of the cavity, and he is instructed to perform repeated forced inspiration and expiration while a long pair of forceps keeps the incision open (Fig. 11) fluid being forced out with each expiration and air forced in with each inspiration, masses of fibrin being removed by the same forceps as they appear in the wound until the entire cavity is thoroughly emptied of fluid and free fibrinous masses. In children the crying efforts are utilized in the same way. If the patient becomes shocked or has a tendency to cough the wound is closed by digital pressure and the patient is immediately relieved. After a moment the procedure is continued as before. When the chest has been entirely emptied the patient takes a final deep inspiration at the end of which the lips of the wound are compressed digitally and kept so by a gauze compress. These wounds do not drain, they heal readily and have to be reopened if the procedure is to be repeated.

This last method may perhaps more readily appeal to many who seem so unreasonably prejudiced against aspiration. They can have as bloody a field as desired, can see the pus pour out, including fibrinous masses, and can reopen the wound at will.

In many of these cases there seems to be no reason to hurry and if one will have the patience to wait the fibrin will eventually liquefy. I have been on the point of making an incision in a number of these patients but after repeated aspirations without using anything intended as a solvent the contents finally became perfectly fluid and it was possible to empty the cavity entirely.

APPLICATION OF METHODS

Whichever of these three methods is used the volume of air replaced is usually the same as that of the fluid removed. It may, however, be varied as indicated. Thus if the cavity is refilling very fast so that more

fluid accumulates than the volume of air absorbed in the same period, less air is replaced, and *vice versa*. Negative pressure, if desired, may be produced by injecting as little air as desired. I have never deemed it advisable to do so. The air *per se* has no therapeutic value. It is merely used (a) to render possible evacuation of all the fluid, and (b) to replace completely the fluid and support the walls of the cavity as before.

Thus the architecture of the cavity, as it were, is not altered and the hydrostatic or rather the physical compression of the lung is undisturbed except that the heavy inelastic fluid mass is replaced by a light elastic air cushion. In the many hundred times that I have introduced the largest available needles into the pleural cavity, I have never witnessed the clinical syndrome spoken of as pleural shock. I believe that this is due to the pains taken to infiltrate thoroughly not only the skin proper but the pleura itself and all the intervening tissue with the anæsthetic solution. I have never used general anæsthesia. No drain, no suction or irrigation in any form is used.

The amount of pus removed may vary from a few cubic centimeters to as much as 3,000 cubic centimeters or more at one time. The procedure is repeated as often as the fluid accumulates, on an average of about every 6 days. The amount of reaccumulation between aspirations is seldom over 300 cubic centimeters and often less, quite in contrast to the large quantities seen when tube drainage is used. Patients leave the operating table feeling relieved and, having had no discomfort during the procedure except for the infiltration of the local anæsthetic, willingly and cheerfully submit to subsequent aspirations.

The cavity has a tendency to get somewhat smaller as the condition improves, partly because of granulation and cicatrization in the angles of the cavity, and partly perhaps because the air is absorbed faster than the fluid reaccumulates so that one may find the diaphragm gradually rising, requiring insertion of the needle in a higher intercostal space at later sittings.

I believe that complete emptying of the cavity is essential to bringing about a cure.

One patient was cured with one aspiration. Some patients have had ten or more. The average has been about four. When the cavity has been entirely emptied the patient's temperature drops to normal in a few hours and he feels greatly improved and is able to eat and up and take an interest in things about him. If the aspiration or evacuation is not immediately followed by this improvement it means that the cavity has not been emptied or that the patient has another cavity or some other serious condition that is making him sick and a diligent effort must be made to find it.

My second patient had three separate cavities the roentgenograms taken after partial emptying showing three separate fluid lines. These cavities communicated with one another and by rolling the patient first one way and then the other we were able to get the fluid from all cavities against one side of his chest wall and aspirate it. In some of these patients there are separate cavities that do not communicate with one another. In 1 case after quite a large cavity had been evacuated and the pus replaced with air the patient continued to have elevated temperature and to look sick. The roentgenograms showed a shadow and aspiration revealed another cavity above the one that had previously been emptied. This was treated the same way and she made an uninterrupted recovery. I have had 3 such cases, in 1 of which there were three separate cavities.

I have for some time adopted the practice of making a small stab in the skin at the site of needle puncture and I believe that this is one reason why I so seldom see a local pustule or abscess following exploration or aspiration. This little stab wound makes possible the introduction of the large needle which one must use without the pain and psychic trauma caused by trying to force such a large needle through unbroken skin.

In a number of cases for periods of as much as 5 and 6 weeks the cavities went on refilling in spite of repeated aspirations with no improvement in the local signs or in the general condition of the patient. These were those in which the infecting focus in the lung continued to pour infection into the cavity. One was a

gunshot wound with a bronchial fistula. The cavity continued to refill until the fistula finally healed after which the patient's improvement was quite rapid. There is nothing to do in such a case but wait until the lesion heals or the bronchial fistula closes. If there be little or no air forced into the cavity through the fistula, and no tendency to tension pneumothorax healing can sometimes be encouraged by increasing the amount of air injected thus further compressing the lung and favoring the closure of an opening or cavity on its surface. If however there is already positive pressure resulting from coughing of air through the bronchial fistula into the cavity this must be relieved by frequent repeated aspiration of air. If the air re-accumulates rapidly with a tendency to displace lung and mediastinum a needle or trocar should be inserted and left *in situ* so as to permit the escape of air from the cavity as it accumulates. These patients must be watched very closely and seen often as death may result if a tension pneumothorax is permitted to progress without relief.

TREATMENT OF SPECIAL TYPES OF EMPYEMA

For the sake of emphasis and at the risk of some repetition I desire to say a few words about three particular types of empyema.

1. *When a large pre-existing pulmonary abscess or empyema pocket ruptures into the clean general pleural cavity.* The sudden rupture into the comparatively clean pleural cavity of the contents of a large fetid gangrenous abscess of the lung and to a lesser extent that of an empyema pocket is accompanied by profound shock and occasionally the patient dies before anything can be done for him. These lesions are analogous to similar ruptures into the peritoneal cavity. Aspiration or small tube closed drainage in any form is here out of the question. Immediate shock should be combated with morphine and cardiac stimulants, intravenous dextrose and transfusion if indicated. As soon as the patient improves sufficiently a wide opening with rib resection should be made at a point best calculated to secure drainage and the pleural cavity thoroughly emptied and cleansed. If necessary by introduction of a suction tip

into the more inaccessible portions. When the pleural cavity has been cleansed as well as possible, large tube drainage should be instituted with all the precautions against open pneumothorax already mentioned. The hour glass balloon of Morelli (Fig. 12) surrounding a large tube should answer the purpose well here, giving free drainage and hermetical sealing with protection of the raw surface of the incision by contact with the balloon.

2 *Pyopneumothorax*. If before incision or exploratory puncture the physical signs and roentgenogram show the presence of fluid and air, one can be quite sure that a bronchial fistula exists. Two factors here complicate the picture: (a) The presence of a continued focus feeding the pus cavity, and (b) spontaneous pneumothorax air finding its way in through the fistula.

For some time to come, and until the fistula closes, the empyema cavity will continue to be fed with infection, and one must be prepared for a longer period of treatment than otherwise, no matter which method of treatment is adopted. *Prolonged* tube drainage in these cases promotes much granulation in the neighborhood of the tube, rendering the walls of that portion of the cavity correspondingly rigid. The entire pleural surface including its visceral layer becomes denser and less yielding as time goes on, so that when eventually the fistula does close, collapse of the cavity is much more difficult than in the more recent case. If the cavity at this stage does not communicate with the outside, as when aspiration and air replacement has been used, the negative force exerted as the remaining air is absorbed, is exerted principally on the lung surface itself. Being a gradual constant force, the soft tissues be they ever so firm gradually yield and the cavity is finally obliterated. If there has been tube drainage, there can be no collapse while the tube is in place, and even when the tube has been removed the negative pull is more apt to reopen the sinus than distend the lung, hence the greater tendency to chronic empyema. By the judicious use of aspiration and air replacement at this stage any fresh accumulation can be removed and sufficient air can be injected from time to time to give the desired gradual diminution in the

size of the cavity. Thus the pull on the lung is gradual and not strong enough to reopen the sinus or bronchial fistula. I have in this way cured at least 2 cases that had had repeated tube drainage.

In an older patient or one who is inclined to be very quiet especially in the absence of severe coughing spells, spontaneous pneumothorax may not be a serious complication. In children, and in nervous, restless individuals, however, in whom coughing is easily incited and may come on in repeated violent spells, great quantities of air may be forced into the pleural cavity, a little with each coughing effort.

If aspiration or any method of closed drainage is used, the patient must be very carefully watched and frequently seen by the doctor treating the case, and the air permitted to escape if its volume grows large or if any sign of pressure or discomfort develops. This may be done by unclamping the tube where one has been inserted, or performing repeated aspiration if aspiration is being done or before drainage has been instituted. If the recumulation of air is rapid, a needle or trocar may be introduced and left in place for a few days. I know of at least one death caused by neglect to observe this precaution.

3 *Purulent mixed infection empyema, complicating pulmonary tuberculosis, or occurring as an incident to transpleural operations*. The former is a very grave condition. It is due to the rupture into the pleura of a cortical tuberculous cavity or abscess, and this lesion must heal or at least its opening into the pleura close before the empyema can be cured. Tube drainage is followed in a very large percentage of cases by chronic empyema. Even closed, small tube drainage is likely to do the same, especially if any form of suction is used, in which case the cortical lesion is thereby prevented from closing and reinfection of the pleura continuously favored and encouraged.

Aspiration with replacement of air is here the ideal treatment. The amount of air introduced may be increased to the amount thought most calculated to compress the lung sufficiently to favor the closure of the cortical lesion on its surface. If, however, this lesion happens to be in a stretched area of lung such

as in a band reaching from the chest wall to the collapsed lung then the more the lung is compressed the more the band becomes stretched and the more closure of any lesion in its substance is prevented. Hence it may become necessary to cut this band away from the chest wall before the empyema can be cured. One might use for this purpose the instrument of Jacobaeus that is used like an operating cystoscope. It is introduced through a large trocar or small stab wound and the band cut with a low power cautery. On the other hand the chest may be deliberately opened through a long intercostal incision and the band cut under direct vision. This seems a formidable procedure but my experience with 1 case (4) makes me inclined to feel that it should be done more frequently. This was a young man with an old fibrotic tuberculous process in the right lung with pyopneumothorax with mixed bacterial infection which resulted in a cure after repeated aspiration and air replacement before and after the incision of a band by open operation.

The intrapleural pneumolysis of Jacobaeus and the open treatment of these bands by free thoracotomy have been done in cases of pulmonary tuberculosis receiving artificial pneumothorax where these bands prevented the complete collapse of the lung. They are considered as somewhat serious procedures, however because of the possibility of the development of purulent mixed infection of the pleura. The same is true of all operative procedures on the lung even in non-tuberculous patients.

If the case just cited is to be taken as a guide and successful operation deemed possible in the presence of empyema, then the onset of an empyema after a transpleural operation should not appear as such a formidable complication. I believe this to be one of the most important uses to which the treatment by aspiration and air replacement will lend itself.

CONCLUSION

In favor of periodic evacuation and air replacement may be said

1 It can be used as a preliminary to any other method without harm.

2 It can be used when other methods have failed. I have done so in two instances.

3 It leaves no scar or deformity especially if a small stab is done before introducing a large needle.

4 Patient is not constantly bathed in pus, not encumbered with apparatus, is up and about most of the time.

5 Less danger of metastatic abscess. Boyd says this is practically impossible in an untraumatized pleura.

6 The cost of many dressings is saved.

7 Least probability of chronic empyema.

8 Least trauma greatest probability of minimum residual pleural adhesions.

9 With proper precaution should be safer and result in lower mortality than any other method.

10 It is especially valuable in the presence of pulmonary tuberculosis.

11 It lends itself admirably to rendering safer all operative procedures within or through the pleural cavity.

Against the method it may be said

1 It should not be used in sudden overwhelming infection of pleura by ruptured abscess, etc.

2 There is the danger of tension pneumothorax. This is I believe, its most serious objection.

3 Chest wall infection is possible. I have seen only one superficial abscess and very few pustules.

4 During the intervals between treatments a certain amount of pus is present, giving fever, malaise, etc. This usually is only evident 1 or 2 days before the next treatment. The patient is practically well the remainder of the time.

5 It requires more frequent contact of surgeon with patient and more frequent re-examination and roentgenograms.

It is impossible to say all that may be said of empyema in any one article such as this. I have therefore, limited myself to a discussion of the truly clinical phenomena which the surgeon meets and must have in mind in treating the patient. Nothing is said of bacteriology and histological or microscopic changes. I have tried to avoid theory clinging as closely as possible to known facts.

I hope I have made it plain that the air replacement method combined with aspiration or with stab wound evacuation is not just another "new discovery aspiration treatment" It is not merely aspiration, it removes the pus and produces the same condition that results after tube or any other drainage that is, a clean cavity filled with air. The cavity is sealed, there is no strain on its walls and the more air present the longer it takes for absorption, and the more time the endothelial surface has to return to normal. It is not necessary therefore to presuppose that there should be any deviation from the normal process of healing in order to bring about a cure by this method.

INFLAMMATION¹SIR GEORGE LENTHAL CHEATLE, K.C.B., C.V.O., F.R.C.S. *London*

AS a teacher I have always had great difficulty in making clear to the student what inflammation really is and where the process ends. Most writers on the subject seem to me to be in the same difficulty. Textbooks on pathology with the exception of Thoma either imply or state definitely that Burdon Sanderson's definition of inflammation is a true one. In 1872 (?) Burdon Sanderson laid down that "inflammation is the succession of changes occurring in a part as the result of injury provided that that injury be not so excessive as to destroy the vitality of the part. This definition has no time limit the nature of the injury is not specified and it includes events that were either well known or only just conceived at the time it was made. As the definition stands, it would include today processes of infection local and general immunity phagocytosis and the repair of damaged tissue. Even the incidence of certain benign neoplasms and of sarcoma and carcinoma could be included. It is so all inclusive that the common saying 'inflammation is the basis of all pathology' would apply. This application would be meaningless, as if it were said that biochemical or nutritional changes were the foundations of all pathological changes. Twenty years before Burdon Sanderson made his historical definition Lister published his classical investigation upon 'The early stages of inflammation which appeared in the Philosophical Transactions of the Royal Society in 1858. Lister conceived that inflammation is a pathological process, and he ended his researches in these words—'whenever in inflammation congestion or in other words, that disturbance of the circulation which is truly characteristic of inflammation exists in any degree the tissues of the affected part have experienced to a proportionate extent a temporary impairment of functional activity or vital change.

Before Lister John Hunter had conceived that inflammation was active in its nature,

and consisted in an exaltation of the affected parts, and that any increase of blood supply that might accrue to an inflamed part would necessarily induce an increased growth, or action of that part, and as a result induce the repair of damaged tissue.

Let me take these notions more in detail.

John Hunter transplanted cocks spurs into their combs. The result was that the spurs grew to enormous size a condition he put down to the greater power of action in the comb than in the leg. As a contributory cause of the excessive growth he said there was no stagnation of blood in the veins of the head.

Hunter also considered that the new blood vessels that are formed in newly extravasated and unliving substance in the healing of wounds stimulated healing by giving "power of action.

Turning to Hunter's transplantation experiment, some years ago I repeated it, and besides transplanting the spurs into the cocks combs, I transplanted them into the subcutaneous tissue of their necks. All these spurs grew to the same extent in the same time in their new situations, and all the growing spurs were provided with a special leash of blood vessels for their nourishment. The explanation of the excessive growth in the spur when transplanted in the comb cannot have been due to the greater vascularity of the comb or to the freedom of the venous return. The same amount of growth took place in the same time in the subcutaneous tissue of the birds' necks. In this plane of tissue there is very little blood supply compared with the normal cock's comb. Nor could the excessive growth in that part be due to its greater power of action than in the leg, unless the subcutaneous tissue of the neck also has a greater power of action. The great increase of size that occurred in the spur when transplanted into the comb and also into the subcutaneous tissue of the neck is capable of another explanation. In these new situations

the spurs were not subjected to the wear and tear of life to which they are exposed in their normal positions

It is difficult to see exactly what Hunter's experiment does prove. Biological laws of function, physiology, heredity and so forth are so interfered with by altering the normal position of a spur that the results of the experiment become too complicated to render an explanation possible without further evidence. For example, if Hunter were right in his conception that the spur grew to so large a size because the comb possessed greater power of action than the leg and because the venous return was more perfect the following question would naturally arise and demand an answer. How is it that a normal comb ceases to grow when it is in possession of so much "power of action" as to be able to induce such enormous growth in another structure?

The reason of the increase of growth in the spurs when transplanted to this new situation is probably more complicated than the one I just now adduced although it may have some bearing on the matter.

I do not believe that Hunter's experiment can be explained by the spur being transplanted into a part where the blood supply is greater than in its normal position. The neck control experiment negatives that explanation. Nor do I believe that there is any evidence in support of the theory that an increase of blood supply will alone induce an increase in growth or an incitement to grow. The incidence and maintenance of normal growth of repair, and of neoplasms depend on many more factors than merely the increase or diminution of blood supply. Yet they may all have this in common viz that the accurate knowledge of what is occurring in one of these instances may have a great bearing on what is occurring in the remaining two.

Turning again to the observations of Lister on 'the early stages of inflammation,' in this paper Lister chiefly limits his observations to showing that an injured blood vessel is dilated to the state of temporary paralysis, that stasis occurs, that red and white blood corpuscles tend to adhere to each other and to the blood vessel walls. Further that the arrest of movement of the cilia of ciliated epithelium and the

cessation of movements of the pigment granules in pigment cells were proofs of impaired functions in the inflamed parts. So far as I am concerned with two additional factors, Lister's conception appears to me to be the essence of inflammation. The additional factors to which I have just alluded are the exudation of plasma and limited emigration of red and white blood corpuscles from the injured blood vessel walls. I cannot understand why Lister did not include these two factors in his description. Waller¹ in 1846 had described them, but no notice was taken of Waller's work until Cohnheim called renewed attention to it in 1867, 1869 and 1873. Exudation of plasma and emigration of red and white blood corpuscles occur *pari passu* with the other changes that Lister described and therefore necessarily should be included in early changes. In fact stasis of the corpuscles in an inflamed area is due to the escape of plasma from the injured blood vessel walls and emigration of red and white blood corpuscles has occurred before stasis takes place.

I did not know Lister until over thirty years after his work on inflammation. By this time his life was fully occupied in teaching the world the results of his epoch making and more recent discoveries. Having settled the matter that inflammation is a pathological process, he was disinclined to open the matter again and did not inform me of the nature of the events he would have included in an investigation into the late stages of inflammation. Lister's conception of inflammation with the addition of the immediate exudation of plasma and a limited emigration of red and white corpuscles, is from my point, the state of inflammation, and there, upon resolution of these changes, the process stops. Inflammation therefore, from my standpoint, forms only one of the effects that may occur after injury to a part. The nature, degree, and duration of the injury seem to me to induce much more vast and complicated events which should not be included in inflammation. These eventful changes in the parts injured may be entirely different from each other and affected and controlled by different problems,

¹London and Edinburgh Philosophical Magazine Vol. xlix, p. 397

while the process of inflammation as I have conceived it remains the same.

Still, I cannot imagine a more dramatic or descriptive term than that of 'inflammation' that was applied by prehistoric observers to a hot swollen red and painful part. Much water has passed under the bridges since the early ages prior to and including the first half of the nineteenth century. Infection and its consequences immunity and infection the normal growth of tissues the repair of tissues and the formation of neoplasms have become separate problems, and yet they are being described at present in the one inextricable tangle of 'inflammation'.

The knowledge of these things, incomplete though it be is so vast and so rapidly accumulating that I feel these facts alone demand their exclusion from the subject of inflammation and that a limit should be put to its action and influence.

I am fully aware that a great deal I have said is purely contentious and may be regarded as being entirely wrong. I admit that it represents only a personal opinion. Yet I believe I shall carry most pathologists with me when I say that the time has come to exclude repair and the formation of neoplasms of all kinds from the subject of inflammation. It is gradually dawning on mankind that they are under such definite and complete control of the body in some instances and under a disturbance of control in others, that they should not be considered under the head of inflammation. Directly one cell begins to divide into two cells a fresh element has been established and although it may be the effect of injury it is not necessarily the effect of inflammation.

Let me go more into detail by speaking of four subjects. The first (a) is repair of tissues the second (b) is the formation of fibroadenomata of the breast the third (c) is the formation of papillomata in the breast and the fourth (d) some local aspects of infection.

a. In the repair of tissues there is an example of organized and beautifully controlled growth. The control is so definite that the growth cannot be explained as being due only to the presence of growth stimulating agents induced by injury. If that were so tumor

formations would be expected rather than definite organized growth. There is also something more at the back of it all than the presence of hormones. Why should epithelial cells which have covered a raw surface cease to multiply on the instant the raw surface has been covered? No more complete control of growth can be imagined than that which is occurring in the tissues of a healing ulcer of the skin. Until it is covered by epithelium an enormous number of blood vessels are provided for the nourishment of the granulation tissue, but directly the ulcer has been covered by epithelium, these newly formed blood vessels begin to disappear and those that remain are only those that are sufficient in number to maintain the nourishment of the part. The co-ordination of the blood supply to the demands of growth and the subsequent maintenance of nourishment is perfectly timed and masterly in execution.

The repair of tissue does not depend upon a haphazard supply of blood vessels. Sufficient nourishment is supplied to meet the demand, and when that demand ceases the number of blood vessels which have become unnecessary spontaneously vanish. Even the formation of keloids is under some kind of control, which is in all probability local and systemic control.

By examining microscopically the fractured ribs of guinea pigs from the moment of injury to 36 days, I have been able to watch all the stages of a healing fracture. Besides learning a great deal more than I knew before, the prolonged and orderly sequence of events convinced me that they could not have been due to inflammation, or to the excretions of stimulating substance of growth due to the injury or to the uncontrolled action of hormones.

How can anybody maintain that so complicated and controlled an event as normal ossification is an inflammatory process?

I arrived at the same conclusions upon examining microscopically the common carotid arteries of cats from the moment they were ligated until 14 days afterward (Figs. 1 and 2).

In uninfected specimens the smallness in number of the emigrated leucocytes is sur-

Fig. 1

Fig. 1 The carotid artery of a cat 7 days after ligation in continuity. *A* Seat of ligation. *B* the organizing blood clot at the site of the injured internal and middle coats of the artery. The shaft of the arrow *B* is passing through an area where the endothelial cells have gone and newly formed connective tissue can be seen growing from the subendothelial connective tissue into the organizing clot *c*. The lumen of the artery.

Fig. 2

of the subendothelial connective tissue extending far along the course of the artery and diminishing the size of its lumen.

prising. The repair of the arterial coats that had been ruptured at the seat of ligation took place from the subendothelial connective tissue and not by multiplication of the endothelial cells. The only multiplication they underwent was in covering the newly formed connective tissue derived from the intima at this spot. Moreover the lumen of the artery at the end of 14 days had diminished by an increase of the connective tissue of the intima immediately beneath the endothelial lining which remained normal and not by the organization of a blood clot as I had previously supposed.

The formation of adhesions are good examples of purposeful growth of cells which appear to be carrying out inherited functions. In this connection I once had the opportunity of examining microscopically an excised bursa patella that had suffered from injury unconnected by infective process. I excised the bursa 10 days after the injury. The inflammation induced an exudation of plasma within the bursal sac. The plasma coagulated and thus formed a mesh work of fibrin. Where the endothelial cells lining the bursa had been rubbed off, the branches of fibrin remained attached to the bursal wall and were contin-

uous with fibrin therein. These attached fibrinous branches became like hop-poles supports for the upgrowth of fibrous connective tissue cells which took along with them blood vessels for their nourishment. The formation of the adhesion was definitely finished by the covering of this growing connective tissue by a layer of endothelial cells continuous with those lining the bursal sac. The remains of the fibrin could still be seen in the centers of the young adhesions (Figs. 3 and 4).

b The neoplasias of the breast, known as fibro-adenomata, may at first appear to be growths that exhibit no control in their formation. The contrary is the fact. They are under some control that cannot be explained merely by inflammation to which their presence is so often imputed. There is often no sign of inflammation. Besides that the signs that are supposed to be indicative of "chronic mastitis" are present in almost every infant breast at birth, and I would not regard the condition as inflammation at all.

First, let me take the fibro-adenomata that appear at puberty. In their simplest states they are formed by precisely the same tissues that are undergoing physiological activity

Figs. 3, left, and 4. The two extremities of an adhesion in the course of its formation. In Figure 3, the fibria of the base of the adhesion and its continuity into the wall of the burnal sac is well shown. Also the mesh work of fibrin with which the burnal sac was filled can be seen above the adhesion. The microscopical specimen was cut from a burna patella that had been injured 10 days before it was excised.

elsewhere in the same breast. New glandular elements of ducts and acini may be formed in these tumors and whether newly formed or not they are usually surrounded by dense layers of pericanalicular and periacinous connective tissue. It is this newly formed pericanalicular and periacinous connective tissue coming in contact with the supporting connective tissues of the breast that gives these tumors the macroscopical appearance of encapsulation. To classify all these perturbed physiological changes as being inflammatory does not seem to me to touch the problem of their existence.

Second let me take the intracanalicular fibro-adenomata, the connective tissue parts of which I have traced to the subepithelial connective tissue. These tumors occur later in life than those of puberty generally about the fourth or fifth decade. The glandular epithelium covering these tumors often dips down into the connective tissue element and forms perfectly developed normal looking acini, which any young breast would be proud to possess. Irregularly planned new breast tissue has been developed in these tumors, the formation of which is under some control even if it be an irregular control.

c. Next, let me take the formation of papillomata in the ducts of the breast. From

small beginnings of stalks of pericanalicular tissue containing the elastica which are covered by epithelium, these stalks coalesce and in many instances papillomata develop into duct tumors consisting of irregularly disposed ducts and acini. These tumors form another example of some disturbance of control and an aborted attempt to form new breast glandular tissue. Nothing can convince me that they are evidence of only inflammation or that inflammation has anything to do with their formation.

d. Lastly let me take evidence on these matters given by the morphological appearances in the subcutaneous tissues that have been inoculated with a culture of *Staphylococcus aureus*, sufficient in dosage and virulence to give rise to a localized abscess that ruptured in 7 days (Figs. 5, 6 and 7).

In this experiment I examined microscopically the whole of the affected area varying from the effects of the immediate inoculation to 10 days afterward. I have described them in detail in Choyce's *System of Surgery* and I need not here repeat them. The impressions I gained from a morphological study of these events were as follows:

1. The course and results of an infection depend primarily upon a balance or an adjustment between the resistance of the host and

Fig. 5. Part of the margin of an acute staphylococcus abscess in the subcutaneous tissue of a guinea pig 4 days after inoculation. A The center of the abscess B the edge of the abscess which in some parts is in contact with the strands of fibrous connective tissue that has already undergone hyperplasia while at others the abscess is still spreading among fat cells C the strands of fibrous connective tissue that are undergoing hyperplasia at some distance from the edge of the abscess

Fig. 6. Part of the margin of the same abscess. The oval and circular spaces are newly formed blood vessels in a line with the arrow B and are situated at the edge of the abscess in the newly formed connective tissue there situated C The center of the abscess C a strand of fibrous connective tissue that has undergone hyperplasia.

chiefly the virulence of the micro-organisms at the actual moment of infection

For example take the rapid death of a host from a generalization of the infection. Here either the resistance of the host is so low or the degree of virulence of the micro-organism is so high, that no time is allowed for the formation of an acute abscess. Hence when an acute abscess forms it can be accounted for only by the existence of an adjustment between the powers of resistance of the host and the degree of attack on the part of the micro-organism.

During the course of even the formation of an acute abscess the process of the host's resistance may become lowered or the virulence of the micro-organism may become increased yet my opening statement remains a sound one. The whole process first of all depends upon the degree of adjustment of factors of host and micro-organism at time of infection.

Again the first thing that occurs in the formation of an acute abscess is the death of tissue with which the infecting agents come into contact

The next thing that is obvious is the tremendous emigration of polynuclear leucocytes most of which are at first killed. However the process of emigration of leucocytes continues.

The third and fourth events are the emigration of lymphocytes and the hyperplasia of the normal strands of fibrous connective tissues that support the subcutaneous fat. These events occur immediately around the developing abscess and by the fourth day they are well established. I do not know whether the inducement of emigration of the leucocytes is the same in a suppurating process as it is in the stage of inflammation due to mechanical injury. If the inducing agents be the same in both processes then it could be claimed that inflammation is a great factor in suppuration.

If however the inducement of the leucocytes to emigrate in a suppurating process be not the same as in inflammation produced by mechanical injury then not in inflammation but some other process is in operation. I doubt very much whether the factors that induce the emigration of leucocytes are the same in infective and non-infective lesions.

The bone marrow in which the enormous increase of polynuclear leucocytes is manufactured, is not in a state of inflammation. In fact, the whole of this part in the formation of an acute abscess may be considered as being

A

Fig. 7. Part of the margin of an acute abscess (*Staphylococcus aureus*) stained by Gram's method, 7 days after inoculation. A The center of the lesion. B the marginal ring of massed staphylococci encircling the edge of the abscess. C the surrounding subcutaneous fat and connective tissue.

questions of immunity rather than being concerned with the process of inflammation. Micro-organisms at first multiply and are mixed with no arrangement in the lesion. By the seventh day a very definite arrangement has occurred in which a dense mass of micro-

organisms completely encircles the abscess cavity in the form of a ring. The ring of micro-organisms is situated at the extreme edge of the abscess beyond which none can be seen. It is impossible to explain the meaning of this ring beyond suggesting it has something to do with the question of immunity (Fig. 7).

Turning to the later events such as the hyperplasia of the normal supporting strands of connective tissue during the process of formation of an acute abscess here again the establishment of immunity transcends in importance any concurrent process of inflammation that there may be.

The hyperplasia of connective tissue that takes place around an abscess could not occur if the micro-organisms were able still to cause the death of tissue they manifested on their first introduction.

An abscess does not get well and does not become localized because it is encysted by an abscess wall. Even when the abscess has been opened and the lesion is getting well, pus can still be seen in tissues where there is no limiting wall.

These observations definitely show that infection and immunity and not inflammation are the important factors the body is concerned with in the formation and cure of an acute abscess.

THE DETECTION OF THE CLINICALLY LATENT CANCER OF THE CERVIX

WITH A REPORT ON SCHILLER'S LUGOL TEST¹

WILLIAM P. GRAVES, M.D., F.A.C.S., BOSTON

THE treatment of cervical cancer is at the present time entering upon a new and more hopeful phase made possible by fresh scientific knowledge both of malignant disease in general and of that particular aspect of it that forms the subject of this paper.

The combat against cervical cancer during the last 30 years has accomplished much. The formidable operations of Wertheim and Schauta which demonstrated the possibility of permanently curing the disease have given way for the most part to the simpler and more efficacious methods of radiation. Elaborate follow up studies of treated cases have formulated the percentage of permanent cures to be expected relative to certain stages of progress of the disease. The total number of cured cases though not large enough appreciably to affect the general mortality statistics, is nevertheless encouraging. It has at least established a fact of prime importance, namely that cancer of the cervix is frequently cured by the means at our disposal, the chances of cure being directly proportional to the timeliness of the attack.

The logical conclusion is that every cancer of the cervix passes through a period in its life history during which it is theoretically one hundred per cent curable. This is the rock on which the hope of controlling the disease is at the present time based. Ultimate success depends on the co-ordinated efforts of every member of the profession who treats women at all to detect and bring to treatment the early case.

Now for the past 30 years we have all been studying and treating cervical cancer in its advanced stages. All clinical and pathological characteristics with which we are so familiar are those of advanced cancer. The standard symptoms of fetid discharge, bleeding, pain, the local changes of tumor formation, metastasis and ulceration, the histological picture of

invasion and multiplication of cells, all are manifestations of comparatively late stages of the disease. The great array of tables portraying the percentages of mortality, recurrence and cure represents almost exclusively the treatment of advanced cancer. The division of cervical cancer topographically is merely an inaccurate estimate of the degree of progress in an already protracted disease.

It is difficult to realize how few incipient cancers of the cervix have until recently ever been detected and consciously treated. Only the merest handful have been reported in the literature, the discovery of such a case being usually by pure accident and hailed triumphantly as the rarest of finds. And yet since the incidence of incipient and terminal cancer is identical, patients must repeatedly be on our examining tables who without impairment of health and often without symptoms harbor a disease which at the same time is invisible to the keenest eye and is tangible to the most sensitive touch.

The treatment of advanced cervical cancer has actually reached an *impasse*. Surgery has attained its peak of usefulness. The limitations of radium are already in sight. Follow up records are now a necessary routine of the clinic but can teach us little that is new concerning the results of treatment along the old lines. The hope of diagnostic immunizing and curative sera must probably be abandoned in the face of scientific evidence that cancer is primarily a local and not a constitutional disease. Metals in colloidal form have proved disappointing since they are too destructive to the normal tissues. In view of the amazing effects of radium we look instinctively to the scientists to discover some new form of radiation in which the human body may be bathed and harmlessly cleansed of all malignant tendencies, an idea not entirely chimerical but certainly at the present moment utopian.

Fig. 1 Photomicrograph showing the abrupt change from normal to cancerous epithelium. The line of demarcation is always oblique since the change takes place in the cells of the basal layer first. The process is therefore further advanced in the lower than in the upper cells. On the left of the line are seen the well ordered layers of the normal epithelium. On the right are seen the dark atypical cells of the cancer. The interpapillary plugs are irregular and chubbier but there is no elevation on the surface nor invasion of cancer cells in the stroma. Note the dense inflammatory infiltration beneath the cancerous portion. The disease is progressing from right to left by assimilation like ink on blotting paper. Taken from Schiller (5, p. 359).

In the search for the early case it must first be recognized that the life history of a cervical cancer covers on an average from 10 to 12 or more years. This includes a long irritative stage of chronic *cervicitis* and a shorter though still protracted period of *clinical latency* during which the cancerous change though actually present does not attract the attention of the patient or her attendant.

Until recently our best means of discovering cervical cancer in its latent stage has been the policy of timely repair of the inflamed cervix with a routine biopsy of the tissues. Many unsuspected cancers may be discovered in this way. But this policy has not been sufficiently widely adopted and there is still an unaccountable reluctance to repair dangerous *cervicitis* until the age of child bearing is passed. Even when rigidly carried out the system has been open to frequent error. The pathologist unfamiliar with the incipient cancer-changes may miss the diagnosis. Or the operator with nothing to guide him may

miss the cancerous area entirely in removing tissue for biopsy.

In recent times the invention of the colposcope by Hinzelmann has been a laudable move in the right direction. But the instrument is expensive requires expert manipulation and is not well adapted to the use of the general practitioner.

In order to meet the difficulties of the situation it is evident that two things are primarily needed first a clearer knowledge of the histological appearance of an early cancer and second some simple test by which the latent area may be accurately located for purpose of biopsy. In the efforts to solve these two fundamental problems the work of Walter Schiller of Vienna stands pre-eminent and has been taken as a basis for this report.

Schiller approached the matter by first studying exhaustively the cervixes of 135 uteri that had been removed by total hysterectomy for causes other than cancer. Cancer itself being unsuspected. In this series of specimens he found 4 cases (2.96 per cent) with microscopic evidence of what he regarded as the earliest stages of cervical cancer. His observations and conclusions from this study harmonize closely with those of other authorities working in the same field and may be summarized as follows:

Fig. 2 Change from normal to cancerous epithelium. Note the oblique line of demarcation. There is chubbiness of the interpapillary plugs, but no elevation or invasion of the cancerous epithelium. (Taken from Schiller.)

Under the stimulation of chronic irritation the cancer process in a manner unknown starts in a single indifferent cell of the basal layer of the epidermis of the portio vaginalis. As has been shown by Carrel Loeb and others the malignant cell at first produces a virus that is capable of inciting malignancy in neighboring normal cells. This process is called *assimilation* and is the first stage of malignancy in cervical cancer. During this stage the growth extends laterally like the spread of a drop of ink on blotting paper. There is at first no thickening or change of consistency in the epidermis so that the affected area cannot be distinguished by sight or touch from the surrounding normal tissue.

A cancerous process thus inaugurated never heals spontaneously but progresses inexorably to what may be called the late stage that of invasion. The cancer now extends by a new force namely by the *multiplication* of its own cells which is so irresistible that it invades and destroys the neighboring tissues. Here we have the late cancer with which we are all so familiar—the nodular thickening, the ulceration and metastasis, the infection, necrosis and fetid discharge and the bleeding from broken or eroded vessels.

The histological picture of an early cancer in the assimilation stage is striking and

Fig. 4. Case of early unsuspected cancer discovered at the Free Hospital for Women by routine biopsy after trachelorrhaphy. Note the oblique line of demarcation, and the intense inflammatory infiltration beneath the cancerous area. Note also that there is no invasion of the stroma and that the cancerous strip of epithelium is actually thinner than the normal portion. The two dark spots in the normal epithelium are not cancer but the tips of papillae in cross section. (Pemberton and Smith.)

characteristic. Most prominent is an abrupt demarcation between the normal epidermis and the cancer, which always appears as an oblique line. On the one side are the normal epidermoid cells in their well ordered three layer arrangement, on the other side are the dark and stormy cells of the cancer with a blurred or broken basal line, above which appears a confusion of cells irregular in size form and staining properties and with little or no evidence of differentiation and layer building. All the other signs of cancer are seen *excepting that of invasion of the stroma* and when this is present the disease is *ipso facto* in the second or advanced stage. Without enumerating the finer details of the picture we may thus recapitulate Schiller's conclusions:

1. Cancer of the cervix starts in the squamous epithelium of the portio near the os and at first spreads laterally i.e., superficially.

2. It always starts in the unbroken epithelium and not in an ulceration.

3. Histologically the chief determining points of diagnosis are first the oblique line of demarcation between the normal and abnormal areas, and second, the anaplastic atypia and polymorpha of the abnormal cells.

Fig. 5. Abrupt change from normal to cancerous epithelium. In this case there appears on the right a beginning of invasion of the stroma but there is no elevation of the surface. (Taken from Schiller.)

Fig. 5.

Fig. 6.

Fig. 7.

Fig. 5 Lugol test. Lacerated hypertrophied cervix. Cancer absent. The normal epithelium of the portio and vagina stains a dark, almost black mahogany color. The everted mucous membrane of the endocervix does not take the stain and appears light red or pink.

Fig. 6 Lugol test. Cancer present. The drawing is from one of the author's cases, and shows the normal tissue taking the dark stain. On the anterior lip is seen a patch of cancer revealed by the Lugol test, where the stain does not take, leaving the area almost white and sharply delineated from the normal tissue. In this case the disease had already reached the multiplication stage as shown by biopsy but

was still sufficiently early to warrant a favorable prognosis for radium or operative treatment. Radium treatment was used.

Fig. 7 Lugol test. Chronic cervicitis. Cancer absent. Drawn from one of the author's cases. On the posterior lip was a light patch very slightly tinged with brown. The edges of the area blended with the color of the normal background instead of being sharply defined from it as in cancer. Biopsy showed an intense cervicitis with some loss of epithelium in the upper layers. On the anterior lip are several Nabothian cysts, which often take a deficient stain on the surface.

But this histological revelation of the earliest appearances of cancer would be of little practical value without the ability to discover the location of a process not distinguishable by eye or touch. To meet this difficulty Schiller has devised an ingenious test which bids fair to be of general clinical value.

The test is based on the discovery by Lahn that the upper layers of the normal epithelium of the portio and vagina contain rich masses of glycogen which disappear when the epithelium becomes cornified or changed by cancer. In the normal living tissue the glycogen of the upper layers of cells is stained in a few seconds a deep mahogany brown by iodine in watery solution (Lugol's). A superficial area of early cancer being devoid of glycogen does not receive the stain and stands out startlingly white or pink against the deeply colored almost black background of the normal tissue.

I can best present the clinical value of this test by describing my own experience with it. I began using it about 9 months ago with half-skeptical curiosity but soon adopted it as a routine procedure on all cervixes in the

operating room and to some extent in office examinations.

During the period 3 early cases have been encountered which in respect to the Lugol test and the microscopic findings correspond to Schiller's dicta. In each case there had been suspicious contact bleeding so that the cases were not as early as some described by Schiller in which the discovery of cancer was made out of an entirely clear sky. However in all of these cases there was no tactile or visual evidence of cancer and in making the biopsy there was no guide to the location of the cancer excepting that of the Lugol test. Without it the specimens for examination would have been removed at random and the diagnosis of cancer might readily have been missed.

Schiller, in 553 clinical tests, found it positive (i.e. stain deficient) in 140 cases, 19 of them showing early cancer.

The test, simple as it seems, is not without its limitations. It appears to be completely reliable when it is clinically negative, that is to say when all the tissues take the normal stain. This claim made by Schiller has been repeatedly confirmed by our own biopsies.

The test is therefore specific for determining the absence of cancer of the portio and vagina. This of itself is an inestimable aid.

But there are several conditions that obscure the test and with these the examiner should be thoroughly familiar.

1 The stain does not take on glandular epithelium like that of the eadocervix. Hence an eversion (ectropion) would appear pink. The same is true of the epithelium of an adenocarcinoma, so that this type of cervical cancer must be sought for in the usual manner. Fortunately such cancer is rare.

2 Ulcerations and erosions do not take the stain since they have no epithelial covering.

3 In areas of chronic cervicitis the epithelium seems often to be deficient in glycogen, taking a very light brown which blends with the surrounding deeply staining tissue instead of being sharply defined from it as in cases of true cancer. We now, after the biopsy, dissect off the suspicious area and close the wound with fine catgut.

4 The normal stain is prevented or obscured by slight trauma such as that from tenaculum or scrubbing with gauze. This is caused by the rubbing off of the upper layers of epithelium in which the glycogen is chiefly deposited.

5 The cervix and vagina of the hypoplastic and atrophic individual stains lighter than the normal. It is especially deep during pregnancy.

6 Pus stains black since leucocytes are rich in glycogen. Necrotic tissue also stains black but clean living granulations do not take the stain. A film of mucus prevents the stain. Blood and douche water obscure the reaction.

7 Hyperkeratosis prevents the stain as in leucoplakia, lues, and exposed areas in prolapse.

8 The test is of limited value in diagnosing advanced cancer, since the superficial assimilation stage is usually lost in the mêlée of self reproducing cells. Sometimes superficial areas detectable by the Lugol test may be found beyond the border of the advanced cancer especially in the fornices of the vagina and this may serve as a guide in determining

the limits for a radical operation. Cancer cells in the advanced stage may regain glycogen and thus give a dark stain with the Lugol's solution. Normal epithelium lying above an invading cancer takes a normal stain as would be expected.

9 Schiller's test is specific for cervical cancer, and is not adapted to other superficial cancers such as those of the vulva and skin in other parts of the body. This is due to the fact that the normal epidermis of the portio and vagina is not cornified and that the upper layers of cells contain a special chemical type of glycogen.

Application. The writer's technique is as follows. A thick swab of absorbent cotton and gauze is prepared on the end of a stout wooden applicator. The swab is first immersed in the Lugol's solution until a copious amount of it has been absorbed. With the upper vagina well exposed by speculum or retractors the swab is then pressed firmly against the anterior lip of the cervix. The upper vagina is in this way flooded with the solution which instantaneously stains the normal tissues (excepting the mucous membrane of the endocervix) almost black. Any area of the portio no matter how small that does not take the stain must be regarded with suspicion. The suspicious area is then curetted with a specially sharpened spoon curette. The strip of epidermis thus secured is placed immediately in hardening solution and sent to the laboratory for biopsy.

CONCLUSIONS

We are finding the Schiller test an indispensable aid in the search for early curable cancer of the cervix. It is specific for the absence of cancer. Failure of the stain indicates certain other abnormal conditions two of which, leucoplakia and intensive cervicitis, are potential precursors of cancer and require treatment. We recommend the test for trial to the general profession.

THE RESULTS OF RADIUM TREATMENT IN FUNCTIONAL UTERINE BLEEDING¹

FLOYD L. KLENE, M.D., F.A.C.S., AND FRANKLIN L. PAYNE, M.D., F.A.C.S. PHILADELPHIA

FROM January, 1920 to July, 1931, 423 cases of functional uterine bleeding were admitted to the Gynecological Department of the University Hospital. Three hundred and ninety-one were given radium treatment and of these complete data regarding its effects upon bleeding are available in 344 and upon menopausal reactions in 336. In all the bleeding was so profuse or prolonged as to demand surgical measures for its control; no organic lesion in the pelvis could be found to explain the bleeding and there were no evidences of a causative constitutional disease, blood dyscrasia, or thyroid dysfunction. A large proportion had received no benefit from medical measures and in 73 the bleeding had persisted after some form of surgical treatment. Fifty-two patients had been curetted, some as many as five times, usually with no benefit or at most relief of from 1 to 6 months duration. None of the patients had received the present day hormonal therapy since the period of observation antedated the availability of these preparations. Doubtless a certain number would have responded favorably to it but our experience has shown that it is by no means a panacea and that at least 50 per cent will require some other form of treatment. Examination under anesthesia and microscopic study of the endometrium were invariably made.

Our experience with radium dates back to 1913 when Dr. John G. Clark began its use

In his clinic and we gratefully acknowledge our indebtedness to him for many of the principles which continue to guide us in this work. As the result of this experience we are convinced of the value of radium in the treatment of benign uterine hemorrhage whether of neoplastic or functional origin but by the same token this experience has enabled us to appreciate its limitations and has engendered a profound respect for its harmful potentialities when injudiciously applied. Accuracy of diagnosis, an understanding of the effects produced by radium in healthy and diseased structures as well as upon ovarian function, the ability to determine what lesions are amenable to irradiation and careful attention to the technique of application are the essentials of successful radium therapy. When these qualifications are met the results are on the whole satisfactory and complications are reduced almost to the vanishing point under other circumstances undesirable sequelae are sure to occur.

Much of the adverse criticism of radium is due to its abuse rather than to its use but even in the hands of those skilled in gynecological diagnosis and familiar with the effects of irradiation unsatisfactory results are encountered. The cure of functional bleeding by radium is accomplished by its effects upon ovarian function, cessation of which may result in the profound and often lasting disturbances which characterize the induced

menopause. For this reason radium should be used only when more conservative measures have failed and then with due regard to its limitations and dangers.

Although radium therapy was the procedure of choice in 92 per cent of the 423 patients, we believe that hysterectomy and roentgen therapy have a place in the treatment of functional bleeding. Radium is preferable to roentgen therapy because its dosage can be more accurately regulated; further completion of the treatment can be accomplished at the time of diagnostic curettage which should precede either form of irradiation. Hysterectomy or roentgen therapy are chosen when radium has failed or some condition is present which contraindicates its use; the choice of the one or the other depending in large measure upon the age or nervous stability of the patient.

The absence of both intermenstrual pain and acquired dysmenorrhea is a characteristic feature of functional bleeding. When pain is associated with irregular bleeding some organic pelvic lesion is usually present even though examination fails to reveal it and operation is preferable to radium therapy. With surprising frequency the wisdom of this decision will be proved when the abdomen is opened.

Radium should be employed with caution if at all, in patients who have had a previous pelvic operation since an intestinal loop adherent to the uterus may be seriously damaged by the rays. In a few instances we have used heavily filtered radium in small dosage successfully but we prefer operation or roentgen therapy.

Patients with profound anemia react poorly to both radium and roentgen therapy and irradiation of either form should be withheld until the blood has been improved by transfusion and other appropriate treatment. In deed, blood transfusion may be a curative measure, as we have had occasion to observe in a few cases of adolescent hemorrhage.

Our confidence in curettage as a therapeutic measure is in direct proportion to the 3 per cent incidence of its use in this series. However it, too, has a place in the treatment of functional bleeding particularly in girls and

young women when one may hesitate to use radium. At least a few will be temporarily benefited or cured. Even though the results be disappointing so far as bleeding is concerned the procedure is not entirely futile since valuable data will be afforded by a study of the endometrium thus obtained.

An attempt to estimate what has been accomplished by radium therapy must take into consideration not only the control of bleeding but also the manifestations of disturbed ovarian function which have arisen incident to its use. The criteria of success or failure vary in accordance with the age of the patient. In young women success is measured in terms of normal menstruation and preservation of the reproductive function, while in women approaching the menopause, the treatment is often a success even when complete cessation of these functional activities occurs. The frequency with which this differentiation must be made is evidenced by the fact that 50 per cent of the patients in the group studied were under 40 years of age. We have approached the problem of evaluating our results with these standards as our guide. The incidence of control of bleeding, permanent amenorrhea, and severe menopausal reactions is the yard stick by which these results are measured.

Throughout this study, we have determined the results from the standpoint of age groups and Table I gives a summary of the percent age of patients in each decade who received a given dosage of radium. According to our present belief, an initial dosage of between 400 and 500 milligram hours in the group under 30 is high nor would we give between 800 and 1200 milligram hours to nearly one fifth of the patients between 30 and 40. During this study, it was our custom gradually to increase the dosage with increase in age and the incidence of 46 per cent shown in the third age group who received between 400 and 500 milligram hours is explained by the fact that the age of the majority of the patients approached the end of the decade. Taken as a whole, comparatively small dosage characterizes this table.

The analysis of dosage outlined in Table I is based on that given at the initial treatment

TABLE I.—DOSAGE OF RADIUM IN RELATIONSHIP TO AGE IN THREE HUNDRED AND NINETY-ONE PATIENTS

Age in years	Number patients	100-200 mgm. hrs. per cent.	200-300 mgm. hrs. per cent.	300-400 mgm. hrs. per cent.	400-500 mgm. hrs. per cent.	500-7,000 mgm. hrs. per cent.
Less than 20		61	31			
20 to 29	84	71	14			
30 to 39	97	1	26			6
40 to 49	163		9	43	48	
50 to 59	30			43	67	

only and the results of this dosage are presented under the first portion of Table II. Under the heading of bleeding controlled are included both return of normal menstruation and permanent amenorrhea, hence a second heading was chosen in order to demonstrate the incidence of the latter condition. As would be expected, the highest percentage of those requiring subsequent treatment is found in the youngest age group and this decreases progressively to 8 per cent in those over 40 years. The last portion of Table II summarizes the final results obtained from both the initial and subsequent treatments.

This analysis forcibly confirms the statement previously made that conclusions as to the value of radium therapy must be based not upon the control of bleeding alone but also upon the incidence of amenorrhea in women under 40 years and severe menopausal reactions at any age. Could we construct an ideal method of treating functional hemorrhage it would have for its results return of normal menstruation and absence of menopausal symptoms in women under 40 and either amenorrhea or normal periods without severe menopausal reactions beyond this age. This Utopian concept can of course, never be realized but it gives us a standard by which to measure our results. Applying this measure of perfection we find that it comes nearest to accomplishment at the two extremes of the menstrual life. Between 30 and 40 years when preservation of ovarian function is desirable control of bleeding is but 5 per cent short of the ideal but in one-fourth of these, control was in the form of permanent amenorrhea. Further one-fifth

TABLE II.—SUMMARY OF RESULTS WITH THE PATIENTS GROUPED ACCORDING TO AGE

		Less than 20 years, per cent.	20 to 29 years, per cent.	30 to 39 years, per cent.	40 to 49 years, per cent.	50 to 59 years, per cent.
Results of initial treatment	Bleeding controlled	81	79	99	91	67
	Permanent amenorrhea	6		26	74	55
	Severe menopausal		4	19	30	3
	Patients requiring subsequent treatment	17	20	19	8	8

	Permanent amenorrhea	8		34	77	55
	Severe menopausal	0	8		31	3

of these patients developed severe menopausal symptoms. During the fifth decade of life the ideal is practically accomplished in so far as the control of bleeding is concerned, but at the cost of severe menopausal reactions in a third of the patients. These distressing and often deplorable symptoms of disturbed ovarian function cannot be ignored.

Table III has been prepared to show not only the incidence of temporary and permanent amenorrhea during the different age groups, but also the results of varying radium dosage in each decade. Irrespective of age or dosage no group was immune to a temporary amenorrhea averaging 5 months in duration and in no group did a permanent amenorrhea develop after a dosage of between 200 and 300 milligram hours. With the exception of the 20 to 30 year group the incidence of permanent amenorrhea increases directly with the radium dosage as would be expected. The generally recognized fact that resistance to the action of radium decreases as the age increases is nicely shown in the 400-500 milligram hour group the exception being the group under twenty. Here an incidence of 63 per cent temporary and a 12 per cent permanent amenorrhea may be of no significance since only 8 patients compose it. However it suggests an increased susceptibility to irradiation as compared with that in women in the next decade. From this analysis it would seem that the ovaries in women between 20

TABLE III — DEVELOPMENT OF TEMPORARY AMENORRHOEA (T) AND PERMANENT AMENORRHOEA (P) FOLLOWING IRRADIATION IN 344 PATIENTS

The Temporary Amenorrhoea Varied Between 3 to 12 Months with an Average of 5 Months

Age in years	3 to 100 mgm. hrs., per cent		4 to 200 mgm. hrs., per cent		6 to 300 mgm. hrs., per cent		8 to 1,000 mgm. hrs., per cent	
	T	P	T	P	T	P	T	P
Less than 20	11	0	63	1	None treated		None treated	
20 to 30	10	0	47	0	None treated		100 (3 patients)	
30 to 40	20	0	40	11	56	21	40	56
40 to 50	None treated		13	37	20	6	3	61
50 to 60	None treated		None treated		17	17	1	90

and 30 are highly resistant to radium or possess a strong recuperative power, since a permanent amenorrhoea did not develop in a single instance, despite the fact that one patient received 1 200 milligram hours. In the next decade, permanent amenorrhoea is noted in 12 per cent, while in the 40 to 50 year group, the incidence rises to 37 per cent after the same dosage which gave none between 20 and 30. The increasing susceptibility to radium after 30 has an important bearing upon initial dosage and will be referred to later.

Table IV shows the incidence of menopausal symptoms, both mild and severe, which developed in the various age groups after the initial dosage summarized in Table I. Although no group escaped the mild reactions these were for the most part transient and cannot be considered an objectionable feature of the treatment. On the other hand, severe menopausal symptoms are noted in all groups except those under 20, rising to a 30 per cent incidence between 40 and 50. The group between 50 and 60 received the largest average dosage, yet severe symptoms occurred in only 3 per cent. A factor, which contributes to the incidence of severe menopausal symptoms, is the patient's unstable nervous mechanism. The more nervous the individual, the greater is the likelihood of a stormy menopause even under normal conditions and when induced by irradiation the severity is multiplied. Bitter experience has taught us that this type of woman is ill adapted to radium therapy and

TABLE IV — DEVELOPMENT OF MENOPAUSAL SYMPTOMS FOLLOWING IRRADIATION IN 336 PATIENTS

Relationship Between the Severity of the Symptoms and the Patients' Age

Severe	0	4	19	10	3
Mild	11	14	5	35	41
Total	11	18	24	45	46

that hysterectomy with ovarian conservation should be chosen in its stead.

The incidence of severe menopausal symptoms, which have followed variations in radium dosage during each decade, is presented in Table V. In general our analysis shows that the percentage of these reactions increases with the dosage and this fact is well illustrated in the 30 to 40 year group which reaches the peak of 47 per cent with what is generally recognized as the menopausal dose. Exceptions are noted in the 20 to 30 and 40 to 50 year groups. Individual variations in the reaction to radium are well recognized and increased susceptibility may afford the explanation of these exceptions. Reference to the last two groups of the table shows that with a given dosage of radium, severe menopausal symptoms decrease with each decade until between 50 and 60 they are almost negligible. This is in direct contrast with the occurrence of permanent amenorrhoea and it has an important bearing on the determination of initial dosage in patients over 40 years of age when a combination of amenorrhoea and a low incidence of severe menopausal symptoms approaches the ideal result.

At the beginning of this discussion, the assertion was made that control of bleeding is not the sole standard by which the value of radium therapy is measured, but that consideration must also be given to the incidence of permanent amenorrhoea and severe menopausal symptoms which may develop from the treatment. The associated incidence of these three factors with varied radium dosage during the different decades is shown in the following tables. The results given are those of the initial dosage only.

TABLE V—THE RELATIONSHIP BETWEEN THE AGE THE DOSAGE AND THE DEVELOPMENT OF SEVERE MENOPAUSAL SYMPTOMS

Age in years	to 200 mgm hrs per cent	4 to 700 mgm hrs per cent	8 to 700 mgm hrs per cent	8 to 1000 mgm hrs per cent
Less than 20			None treated	None treated
20 to 30			None treated	
30 to 40		7		47
40 to 50	None treated	1	8	98
50 to 60	None treated	None treated		8

The group of 17 patients under 30 was about equally divided between the two dosages given (Table VI). Although the incidence of temporary amenorrhoea was high with the larger dosage only one patient developed permanent amenorrhoea and the bleeding was not controlled in approximately half of them.

Between 20 and 30 years of age menstruation was restored to normal in a much higher percentage (Table VII). Permanent amenorrhoea did not develop but an incidence of 4 per cent severe menopausal symptoms is noted with the smaller dosage. The isolated instances of permanent amenorrhoea without menopausal symptoms and severe menopausal symptoms without amenorrhoea exemplify the individual and unexplainable reactions which may follow irradiation.

Table VIII is particularly interesting because in this 30 to 40 year group an opportunity is afforded to demonstrate the effects produced by variation in radium dosage as well as to support our contention that evaluation of radium therapy must be made in terms of permanent amenorrhoea and severe menopausal symptoms as well as control of bleeding. The results are on the whole satisfactory in so far as the control of bleeding is concerned but with the exception of those obtained from the minimal dosage the toll exacted by permanent amenorrhoea and severe menopausal symptoms has been high. At an age when the preservation of ovarian function is of vital importance such results cannot be considered successful irrespective of what the effect on bleeding has been.

The group between 40 and 50 comprises 147 patients. Permanent amenorrhoea is a de-

TABLE VI—ANALYSIS OF THE LESS THAN 20 YEAR GROUP BASED UPON INITIAL DOSAGE AND RESULTS

Dosage mgm hrs	Bleeding controlled, per cent	Permanent amenorrhoea, per cent	Severe menopausal symptoms
0-200	55		
4-700	50		

sirable result during the fifth decade and we find that with a dosage as small as 400 to 500 milligram hours it has occurred in 57 per cent and the bleeding has been satisfactorily controlled in 86 per cent. Practically the same figures obtain with increased dosage until we reach the 800 to 1200 milligram hour group when the results are but little short of perfection. However final judgment must be withheld until the results are measured in terms of severe menopausal reaction. Although the incidence of 31 per cent with the minimal dosage is significant we have reason to believe that the figures obtained by our analysis of the two larger groups are more dependable. Here we find that the dosage usually employed meets expectations in the control of bleeding but that severe menopausal symptoms will be the price for such relief in 38 per cent of the patients. With reduction of the dosage to between 600 and 700 milligram hours, the incidence of these distressing symptoms is reduced one-half yet the bleeding is controlled satisfactorily in but 10 per cent less than with the larger dosage.

Twenty seven patients were between 50 and 60 and in this group the results come nearest to the ideal. The low incidence of severe menopausal symptoms as compared with that of the preceding decade is a striking feature of this age.

COMPLICATIONS

Of the 391 patients treated 1 died from Vincent's angina 7 days after irradiation. Two others developed a pelvic cellulitis with abscess formation in 1 and both recovered. The only other complication noted was femoral phlebitis in 1 patient. This low incidence of mortality and morbidity is a strong argument in favor of radium therapy. As to remote developments, a rectal ulcer was ascribed to irradiation in 1 and a second patient 21 years

of age developed carcinoma of the fundus $3\frac{1}{2}$ years after the primary irradiation at which time the curettings showed hyperplasia

DEDUCTIONS FROM OUR STUDY

The ultimate purpose of a study such as this is to obtain data upon which comparison with other forms of treatment can be made and we shall apply the results of this analysis to that end. A discussion of medical and hormonal therapy in functional bleeding is not within the province of this paper. We have previously referred to curettage and roentgen therapy thus leaving for comparison hysterectomy with conservation of the ovaries and radium therapy.

Although uterine bleeding is the only symptom presented for relief its control is by no means the sole standard by which to gauge the efficiency of a given method of treatment. Were it so either hysterectomy or irradiation could accomplish the purpose equally well. Disturbance in function must be taken into consideration indeed this is in large measure the determining factor in judging the efficiency of either method of treatment.

With this conception constantly in mind we have reviewed our results in radium therapy. We have reported a morbidity of 0.76 per cent and 1 death for which the method could not be held responsible. Hysterectomy has not been performed by us in a sufficient number of patients with functional bleeding to permit of comparison but we know our results from hysterectomy with ovarian conservation in uncomplicated myoma in which the nature of the operation and the condition of the ovaries are identical. Hysterectomy will give a morbidity of approximately 10 per cent and a mortality of 0.5 per cent. Even with ovarian conservation severe menopausal symptoms will occur in about 7 per cent, when

TABLE VIII—ANALYSIS OF THE 30-40 YEAR GROUP BASED UPON INITIAL DOSAGE AND RESULTS

Dosage mms. hrs.	Bleeding controlled, per cent	Permanent amenorrhoea, per cent	Severe menopausal symptoms, per cent
2-100	80	0	0
4-100	87	1	7
6-700	90		24
8-700	91	10	47

the uterus has been amputated sufficiently high to permit of menstruation the menopausal symptoms are largely eliminated. With hysterectomy the reproductive function is lost and the onset of the menopause will be earlier than normal.

Since the occurrence of severe menopausal symptoms will be stressed in this comparison a word concerning them is in order. Because of their frequency and severity they constitute the most formidable objection to irradiation. For some reason we are unable to explain the symptoms are more intense and more persistent in the irradiation menopause than in the surgical.

With these facts in mind the relative value of radium therapy and hysterectomy will be considered during each decade.

With radium therapy in women up to 30 years of age menstruation was restored to normal or nearly normal in 88 per cent, permanent amenorrhoea developed in 6 per cent and severe menopausal symptoms in 8 per cent. One patient developed phlebitis and 1 died from Vincent's angina. Of the 40 married women in this group 5 gave birth to normal babies and 8 had miscarriages subsequent to their irradiation. The evidence in favor of radium therapy at this age is so apparent as to make further discussion unnecessary.

Between 30 and 40 the picture changes. Although the bleeding was controlled in 95 per cent, permanent amenorrhoea developed in 24 per cent and severe menopausal symptoms in 21 per cent, this occurred at an age when preservation of ovarian function is of vital importance. Our analysis shows that increased susceptibility to irradiation begins after 30 and gradually increases, reaching its

TABLE IX.—ANALYSIS OF THE 40-50 YEAR GROUP BASED UPON INITIAL DOSAGE AND RESULTS

Dosage mgh. hrs.	Bleeding controlled, per cent	Permanent amenorrhea, per cent	Severe menopausal symptoms, per cent
0-100	86	87	3
0-200	87	82	19
0-300	97	82	38

height in patients who continue to menstruate after 50. Further that the incidence of permanent amenorrhea and severe menopausal symptoms is parallel until 40 when, as amenorrhea increases, severe menopausal symptoms decrease. These facts are of importance in this age group because of their bearing upon the selection of dosage in case re-radiation becomes necessary. We have found that with an initial dosage of between 200 and 300 milligram hours the bleeding is controlled in 80 per cent with no permanent amenorrhea and no severe menopausal symptoms. With gradual increase in dosage there is a rapid increase in the menopausal reactions until with 800 to 1,200 milligram hours, permanent amenorrhea occurred in 56 per cent and severe menopausal symptoms in 47 per cent.

In fairness to radium therapy let us analyze the initial dosage in this group. We find that the average dosage was much larger than it should have been and the conclusion is warranted that these unsatisfactory results are due not so much to the fault of the method as to its application.

In this group 70 married women gave birth to 6 normal babies and 4 miscarried. Two patients developed a pelvic cellulitis, 1 going on to suppuration and there were no deaths.

We believe that with a reduction of the initial dosage to 300 milligram hours and an increase of not more than 100 milligram hours, in case re-radiation becomes necessary, radium therapy is the method of choice in this group. Should this fail we favor operation with preservation of ovarian function rather than increased irradiation.

Functional bleeding occurs most frequently between 40 and 50 years of age and because these women are approaching the time when,

TABLE X.—ANALYSIS OF THE 50-60 YEAR GROUP BASED UPON INITIAL DOSAGE AND RESULTS

Dosage mgh. hrs.	Bleeding controlled, per cent	Permanent amenorrhea, per cent	Severe menopausal symptoms, per cent
0-100	100	77	
0-200	90	90	6

in the normal course of events, functional activity will cease the administration of a menopausal dosage of radium has come into common usage. Our results show that with such an initial dosage, bleeding will be controlled in 97 per cent but with a severe menopausal reaction of 38 per cent. Reduction of the dosage to from 600 to 700 milligram hours will control the bleeding in 87 per cent and bring the incidence of menopausal symptoms down to 19 per cent. A 400 to 500 milligram hour dosage gives practically identical results so far as control of bleeding and permanent amenorrhea are concerned. As previously stated, its increased incidence of severe menopausal symptoms can be discounted in favor of that shown in the higher dosage group.

We do not know the incidence of severe menopausal symptoms under normal conditions but it probably lies between 5 and 10 per cent with an 800 to 1,200 milligram hour dosage the bleeding will be controlled in 97 per cent but as the direct result of this treatment, the nervous stability will be seriously impaired in one-fourth of these women who would otherwise have escaped it. With a dosage of from 600 to 700 milligram hours, the incidence of severe menopausal reactions is reduced to 19 per cent but this, too, is high. Our experience with a maximum dosage of 400 milligram hours is not sufficient to warrant conclusions, but the evidence indicates that it would still further lessen the incidence of these reactions and at the same time control the bleeding in over 80 per cent.

So impressed are we by the results of this study that we propose to give the 400 milligram hour dosage a trial in women near 40 years of age. Should this and a re-radiation dosage of 500 milligram hours fail we believe operation should be considered because in the end, it is a more conservative measure than

increased irradiation. In women near 50, increased radium dosage or roentgen therapy can be used because the incidence of severe menopausal symptoms will more nearly approximate that of the uninduced menopause.

Between 50 and 60 years of age the results of radium therapy approach perfection. Maximum dosage can be given almost with impunity since severe menopausal reactions develop in but 3 per cent.

Based upon this study, certain general conclusions seem warranted. The value of radium therapy must be measured not only in terms of bleeding control but also of the menopausal

reactions which are produced by it. The deductions afforded by this study regarding these factors during the different decades and from graduated radium dosage, might be modified to some extent by a similar study of larger groups but sufficient evidence is offered to prove the value of small initial dosage up to 50 years of age and the dangers of large dosage. When other measures have failed to control functional bleeding, radium therapy is the best method at our command, but it has its limitations and should not be used to the exclusion of operation when these limitations have been reached.

MEDICINE AND SURGERY IN INDUSTRY¹

FREDERIC A. BESLEY, M.D., F.A.C.S., WAUKESHA, ILLINOIS

Chairman, Board on Industrial Medicine and Traumatic Surgery

IT is axiomatic that the value of the individual to society depends largely upon his health freedom from disabilities and his feeling of security in the knowledge that death is postponable.

When attempting to elucidate this complex and involved subject of medicine and surgery in industry one is confronted with his narrow limitations. We have sufficient knowledge to clarify this situation theoretically but have we the necessary practical wisdom to utilize this knowledge intelligently in bringing about a solution of some of the vital problems?

Several years ago Dr. Franklin H. Martin, director general of the American College of Surgeons, observed that the subject is a most important one and someone must do something about it. With his characteristic vision, his courage and his prompt action he established a Board the function of which was to make an accurate comprehensive and complete study of the entire subject of industrial medicine and traumatic surgery that the knowledge so gained might aid us in wise and judicial decisions for the betterment of all the involved interests. During the past year he has sent two excellently trained men into the field for the purpose of making a first hand fact finding study of the activities of industrial clinics in all their medical surgical and economic aspects. Some of the data thus secured might have been ascertained from information and statistics previously compiled and yet, as a basis for the formulation of a definite proposed plan and program there is no knowledge so valuable as that obtained by a first hand survey.

Upon the data thus secured it is proposed to approve such medical set ups in industry as shall conform to the minimum standard for such departments as it has been established by the College.

As a preamble in the consideration of the problems involved in industrial medicine three essential basic principles present themselves.

First the health, happiness, efficiency and general mental and physical welfare of the employee. This is the paramount object.

Second the protection of the rights and the ethical standards of the physicians in their relation to the worker in industry. All of these principles must be safeguarded.

Third the direct and indirect economic saving that will accrue to the employer, the employee and to society at large if intelligent scientific surgical and medical care is given to the employees and their families.

Is there any conflict of interest in a joint consideration of these principles? In this rapidly changing era of our present day civilization has the time arrived when these stated principles must be intelligently considered and plans perfected for their more effective application? There is no paradox in such a consideration and the community of interests demands that thought be devoted to it.

During the past few years a vast amount of literature has appeared in the medical and lay press relative to the alleged high cost of medical care and hospitalization. Extensive surveys have been made and comprehensive data secured and tabulated on this subject. There appears to be a popular psychology and a generally accepted opinion that these costs are too high. Will a careful and accurate analysis of this whole situation confirm this opinion? We believe it will not and that it is a debatable question.

Apparently what has happened is that the present extent and cost of the means and the methods employed in arriving at an accurate scientific diagnosis and the applying of the proper therapeutic measures to the sick and injured patient have evolved and increased beyond the ability of the average patient with an average income to pay this medical expense as an individual. Will it be possible to formulate and to put into execution some plan or program whereby this ever increasing cost can be met by society in some collective arrangement? Is this the crux of the problem?

No one will agree with the thought that the scientific methods now employed should be abandoned or curtailed, or that all of the people in all walks of life should not enjoy the benefits of the best in medicine and surgery. All the sick are not receiving adequate care under present conditions. Our present system of caring for the sick and injured leaves much to be desired. The value of health welfare of workers in industry in a community in a municipality in a state in a nation, transcends any other consideration.

Complete examinations of the men made during the drafts for the army in the late war revealed that large numbers approximately one third were wholly unfit for duty. Similar examinations made of the men now engaged in the army of industry would show a greater proportion of unfit and handicapped.

Are proper remedial measures being taken by industry to correct this unfortunate condition? No! How simple the logic and the deduction that no organization can be stronger and more efficient than the individuals that compose it. The measure of the constructive work that has been done for the health of employees in industry during the past few decades is the condition of their health at the present time as compared to the past. There may have been some improvement but certainly that improvement is infinitesimal. Organized medicine has an unalterable duty in exerting every effort to evolve a far seeing plan to remedy existing conditions and to employ every known method in an attempt to improve the health welfare of employees in industry.

What of this whole situation as it relates to the material self interests of the physician about which there is so much discussion at the present time?

During the past few decades industrialists have made an effort to establish medical departments in their industries and as a result of this activity there came into existence the name 'industrial surgeon,' to designate the physician who assumes the administration of these departments. Unfortunately, in the earlier years some criticism arose of the ethical methods of these men because they were considered contract surgeons and it was reasoned

that they employed unfair methods in competition with their fellow practitioners. Fortunately some of this has passed and it is now recognized that many of these industrial surgeons had broad far reaching vision and that they were worthy pioneers in the advancement and promotion of better medicine and surgery as it pertains to the worker in industry.

It is within the scope of discretion to venture the opinion that the fellows of the American College of Surgeons have been ignorant of the potentialities in industrial medicine and surgery. Bias and prejudice have played a large part in this indifference. This attitude is changing and a keen interest is developing rapidly in all phases of industrial medicine. Obviously there can be no advancement made in medicine unless the material interests of the profession are protected and conserved and this must not be forgotten in any thought of medicine and surgery in industry.

Can not some plan be promoted whereby all the physicians in any industrial community may profit by and partake in any and all of the activities in medicine and surgery that in industrialists may be stimulated and inspired to initiate? We believe it can and one concrete suggestion occurs to us. Given a community in which there may be several small or one large industry, it should be possible and feasible to induce the executives of industry to subsidize and partly support a semi public diagnostic clinic to which all of the physicians of this locality should have access and where all patients might receive the advantages of trained technicians and complete laboratory examinations. This at a cost within the reach of all. Naturally this would result in an advantage to the patient the physician, and incidentally the industrialists would profit financially to an extent that is difficult to estimate or overstate.

Think of the vast if intangible, financial gain that would accrue to industry if any given industrial community could be made healthier and the health welfare and happiness of that area conserved and protected. Again it is not possible to estimate accurately the increased working power of the men under such a condition.

This is but one of the many arrangements that could be put into effect adding to the profit of the physician in financial gain and educational advancement.

Is it not the unquestioned duty and privilege of the fellows of the American College of Surgeons to become vitally interested in this subject of medicine and surgery in industry and to pursue a study of the entire situation so that a solution of some of the problems may be arrived at through the combined opinion, judgment, and effort of the carefully selected men composing this great organization. The measure of the success of any of the proposed solutions of the mooted questions in the situation of medicine and surgery in industry can be expressed in terms of the advantages that will accrue to the worker the physician and to industry.

How will leaders of industry benefit and how can we as physicians secure the largest measure of co-operation from these leaders in any proposed plan for better medical and surgical care for the employee?

No appeal should be made to these executives on the basis of philanthropy nor should there be an appeal to capitalistic greed but the appeal should be made on sound financial judgment and business sense which will demonstrate an advantage and profit to all branches of society. In the past there has been a tendency in industry to devote a disproportionate amount of thought and capital to the care of the injured rather than to the sick or handicapped worker. The magnificent work of the National Safety Council has resulted in such an enormous decrease in industrial accidents that there is an ever declining necessity for surgery in industry. How much larger and more important is the field of medicine as it applies to industrial relationships.

Some of the larger industrial organizations have a most efficient and effective medical department and have achieved striking results from their activities. It is to be noted how ever that only a small percentage of all employees are engaged in organizations employing five hundred or more men. Data taken from the United States Bureau of Census report 1929 shows the following over 95,000

plants employed 1 to 5 persons each 194,266 plants employed 1 to 100 persons each. The total number of wage earners employed in these plants is 2,581,578 and it is safe to say that a vast number of employees in these smaller plants receive no medical supervision as a group or that the care provided is entirely inadequate.

A word about some of the practices now employed may be constructive. In many plants particularly the smaller ones, the medical department consists of a few dressings and drugs and possibly a separate room known as the first aid station. If such an arrangement is under the control of a competent surgeon, it may serve a useful purpose but all too often it is presided over by an untrained, unskilled fellow employee, not even a trained nurse being employed. The statement that such a plan is a vicious practice cannot be controverted. Under such conditions attempts are frequently made by these unskilled people to remove foreign bodies from the eye which are imbedded in the cornea, or another common procedure is the unsuccessful effort to remove a splinter of wood from beneath a finger nail. Corneal ulcers and infected fingers are the result, with the subsequent loss of an eye, a finger or a hand. Trained nurses in charge of these so called dressing stations who are not controlled by a competent medical adviser are of questionable value.

One of the worst influences that has grown up in the medical departments of industry and in the contacts with insurance companies in workmen's compensation cases is the interference by the personnel man at the plant and the claim agent in insurance. These men all too frequently dominate the situation and control any and all medical activities. Their motive is prompted by the narrow minded desire for immediate financial gain.

This condition of affairs must be combated and changed if advancement is to be accomplished. Until the late war a similar condition existed in fighting armies. The general staff officers were in supreme control of the welfare and disposition of the soldiers. The medical officer was relegated to the subordinate position of caring for the sick and

wounded, controlled of course by the general staff officer. The medical officer had no voice in the location of a camp or base area and often his comments or advice as to water and food supply went unheeded. The staff officer was interested as he thought only in the man at the front fit for duty. The sick and wounded were not his vital concern.

Think back to the time of the occurrence of typhoid fever dysentery tetanus and the scandal regarding the food supply that existed during the Spanish American War. The Civil War, Boer War and previous wars all had similar difficulties. All this was changed during the World War. It was recognized early in the conflict that victory would depend upon man power as measured in terms of numbers morale and health welfare. The wise leaders and administrators immediately conceived the plan of securing the best and most scientific medical and surgical talent that was available and of giving these men sufficient authority to direct and control the health welfare of the troops. The medical profession came into its own.

What was the result? No typhoid no dysentery, no tetanus and the morale of whole armies raised by the knowledge that if injured they would receive the most prompt skillful scientific surgical care possible.

You are all familiar with the excellent medical organization in our own army. The untiring efforts and administrative and executive ability of General Gorgas and Dr. Franklin H. Martin, our own director general were responsible for the securing of the loyal support of all branches of the country's medical activities. The Secretary of War Newton D. Baker had a sympathetic understanding of the requirements and gave his unqualified approval to the recommendations of these men. This is a matter of historic record. The benefits derived from such an organization, in the preservation of the health of the men in the army and in the skillful care given to them when wounded, cannot be overestimated.

Can the circumstances and conditions involved in considering the effectiveness of an army of soldiers equipped for war be compared to those of the peace time army of industry?

Are the great captains of industry assuming the same attitude toward the medical profession that was formerly assumed by the general staff officers toward the army medical corps?

If these questions can be answered in the affirmative and we believe they can then it is our unqualified duty to elicit the support of every medical man in conceiving and executing a remedial plan. Great industrialists are intelligent leaders who are amenable to logic and reason. It should not be difficult with the accurate and extensive statistics that are now available to convince these men of the financial advantages and profit that will accrue to their stockholders if the health welfare of their employees can be conserved and improved.

It is conservatively estimated that 360 000 000 working days are lost to industry through disabilities due to sickness or at a rate of \$3.00 per day over \$1 000 000 000 (one billion dollars) are lost yearly from illness.

Nearly all large industries are at the present time spending vast sums of money in what is known as their research departments and yet the results from the expenditures of these millions are frequently not immediately evident or tangible. Should it be difficult to convince the executives of industry of the large financial advantages of maintaining a research medical and surgical department to study methods and means for improving the health of their employees? It is our conception that a united effort on the part of the medical profession in collecting data on this subject would result in securing the most convincing evidence with which to demonstrate that the establishment of a health research department in all large industries would result in an enormous economic saving to the employer. The employee and society at large would most certainly profit. Consider one concrete condition, the so called ordinary cold. Try to imagine how much economic waste occurs from this prevalent infirmity resulting in labor turnover and in rearrangement and shifting that must occur within any given department when employees are absent or at work and not functioning efficiently. How many times this concrete example could be repeated by citing other health conditions

This is but one of the many arrangements that could be put into effect adding to the profit of the physician in financial gain and educational advancement.

Is it not the unquestioned duty and privilege of the fellows of the American College of Surgeons to become vitally interested in this subject of medicine and surgery in industry and to pursue a study of the entire situation so that a solution of some of the problems may be arrived at through the combined opinion, judgment, and effort of the carefully selected men composing this great organization. The measure of the success of any of the proposed solutions of the mooted questions in the situation of medicine and surgery in industry can be expressed in terms of the advantages that will accrue to the worker the physician and to industry.

How will leaders of industry benefit and how can we as physicians secure the largest measure of co-operation from these leaders in any proposed plan for better medical and surgical care for the employee?

No appeal should be made to these executives on the basis of philanthropy nor should there be an appeal to capitalistic greed, but the appeal should be made on sound financial judgment and business sense which will demonstrate an advantage and profit to all branches of society. In the past there has been a tendency in industry to devote a disproportionate amount of thought and capital to the care of the injured rather than to the sick or handicapped worker. The magnificent work of the National Safety Council has resulted in such an enormous decrease in industrial accidents that there is an ever declining necessity for surgery in industry. How much larger and more important is the field of medicine as it applies to industrial relationships.

Some of the larger industrial organizations have a most efficient and effective medical department and have achieved striking results from their activities. It is to be noted, however that only a small percentage of all employees are engaged in organizations employing five hundred or more men. Data taken from the United States Bureau of Census report 1929 shows the following over 95,000

plants employed 1 to 5 persons each 194,206 plants employed 1 to 100 persons each. The total number of wage earners employed in these plants is 2 581 578 and it is safe to say that a vast number of employees in these smaller plants receive no medical supervision as a group or that the care provided is entirely inadequate.

A word about some of the practices now employed may be constructive. In many plants, particularly the smaller ones the medical department consists of a few dressings and drugs and possibly a separate room known as the first aid station. If such an arrangement is under the control of a competent surgeon, it may serve a useful purpose but all too often it is presided over by an untrained, unskilled fellow employee, not even a trained nurse being employed. The statement that such a plan is a vicious practice cannot be controverted. Under such conditions attempts are frequently made by these unskilled people to remove foreign bodies from the eye which are imbedded in the cornea, or another common procedure is the unsuccessful effort to remove a splinter of wood from beneath a finger nail. Corneal ulcers and infected fingers are the result, with the subsequent loss of an eye, a finger or a hand. Trained nurses in charge of these so called dressing stations who are not controlled by a competent medical adviser are of questionable value.

One of the worst influences that has grown up in the medical departments of industry and in the contacts with insurance companies in workmen's compensation cases is the interference by the personnel man at the plant and the claim agent in insurance. These men all too frequently dominate the situation and control any and all medical activities. Their motive is prompted by the narrow minded desire for immediate financial gain.

This condition of affairs must be combated and changed if advancement is to be accomplished. Until the late war a similar condition existed in fighting armies. The general staff officers were in supreme control of the welfare and disposition of the soldiers. The medical officer was relegated to the subordinate position of caring for the sick and

wounded, controlled, of course by the general staff officer. The medical officer had no voice in the location of a camp or base area and often his comments or advice as to water and food supply went unheeded. The staff officer was interested as he thought only in the man at the front fit for duty. The sick and wounded were not his vital concern.

Think back to the time of the occurrence of typhoid fever, dysentery, tetanus and the scandal regarding the food supply that existed during the Spanish American War. The Civil War, Boer War, and previous wars all had similar difficulties. All this was changed during the World War. It was recognized early in the conflict that victory would depend upon man power as measured in terms of numbers, morale and health welfare. The wise leaders and administrators immediately conceived the plan of securing the best and most scientific medical and surgical talent that was available and of giving these men sufficient authority to direct and control the health welfare of the troops. The medical profession came into its own.

What was the result? No typhoid, no dysentery, no tetanus and the morale of whole armies raised by the knowledge that if injured they would receive the most prompt, skillful, scientific, surgical care possible.

You are all familiar with the excellent medical organization in our own army. The untiring efforts and administrative and executive ability of General Gorgas and Dr. Franklin H. Martin, our own director general, were responsible for the securing of the loyal support of all branches of the country's medical activities. The Secretary of War, Newton D. Baker, had a sympathetic understanding of the requirements and gave his unqualified approval to the recommendations of these men. This is a matter of historic record. The benefits derived from such an organization, in the preservation of the health of the men in the army and in the skillful care given to them when wounded, cannot be overestimated.

Can the circumstances and conditions involved in considering the effectiveness of an army of soldiers equipped for war be compared to those of the peace time army of industry?

Are the great captains of industry assuming the same attitude toward the medical profession that was formerly assumed by the general staff officers toward the army medical corps?

If these questions can be answered in the affirmative and we believe they can, then it is our unqualified duty to elicit the support of every medical man in conceiving and executing a remedial plan. Great industrialists are intelligent leaders who are amenable to logic and reason. It should not be difficult with the accurate and extensive statistics that are now available to convince these men of the financial advantages and profit that will accrue to their stockholders if the health welfare of their employees can be conserved and improved.

It is conservatively estimated that 360,000,000 working days are lost to industry through disabilities due to sickness or at a rate of \$3.00 per day, over \$1,000,000,000 (one billion dollars) are lost yearly from illness!

Nearly all large industries are at the present time, spending vast sums of money in what is known as their research departments and yet the results from the expenditures of these millions are frequently not immediately evident or tangible. Should it be difficult to convince the executives of industry of the large financial advantages of maintaining a research medical and surgical department to study methods and means for improving the health of their employees? It is our conception that a united effort on the part of the medical profession in collecting data on this subject would result in securing the most convincing evidence with which to demonstrate that the establishment of a health research department in all large industries would result in an enormous economic saving to the employer. The employee and society at large would most certainly profit. Consider one concrete condition, the so called ordinary cold. Try to imagine how much economic waste occurs from this prevalent infection, resulting in labor turnover and in rearrangement and shifting that must occur within any given department when employees are absent or at work and not functioning efficiently. How many times this concrete example could be repeated by citing other health conditions

It is recognized that only the social and economic aspects of medicine and surgery in industry have been presented. The assumption is that the fellows of the American College of Surgeons are well versed in the professional phase of this all important situation.

Leaders in any human accomplishment are men of character men with ambition men with vision men with courage and men endowed with the untiring energy and persistent application to the work necessary in their efforts to achieve their desired end. Such leaders constitute the selected membership in this organization. You fellows of the American College of Surgeons are leaders of influence in your respective communities. We appeal to you to go back home and exercise that leadership. Become representatives of the College in your daily contacts with industrialists large and small and sell to them a far seeing program for the standardization and rationalization of better medicine and surgery in industry.

Such a program proposes and comprises the following:

1 The education of the industrialists so that they will come to recognize the financial saving and gain that will be shown by increased profits and dividends if their human machinery can be made to function more efficiently because of better health and strength.

2 To carry the thought to organized medicine that their self interests, both immediate and remote will be conserved and enhanced with the establishment of proper medical and surgical departments in industry controlled and regulated by the leaders in the medical profession so that their financial remuneration and ethical standards shall be maintained.

3 The employee, whose welfare is the paramount issue needs no further education or convincing for he understands that he will be the beneficiary. Organized labor is already committed to such a plan. The American College of Surgeons pledges itself to the promotion of such a plan.

May we say to each and every one of you that this is your opportunity and the responsibility for the success of such an undertaking is yours.

FRACTURES AND DISLOCATIONS IN THE REGION OF THE ELBOW

PHILIP D. WILSON, M.D., F.A.C.S. Boston
 From the Fracture Service, Massachusetts General Hospital

FRACTURES and dislocations in the region of the elbow are extremely common and on account of the toll of deformities and disabilities they have levied in the past have won a reputation for formidableness that is scarcely equalled. Although much has been written about these injuries there still remain sufficient gaps in our knowledge to justify further study of them. It will be our purpose in this article to present a more or less comprehensive view of all the different lesions that are designated by the title "Fractures and Dislocations of the Elbow." Many of the injuries are multiple and it is only by including all in the study that an accurate picture can be presented of the whole.

For the purpose of gathering material we have reviewed the records of 352 patients with 439 fractures or dislocations of the elbow that have been treated by the staff of the fracture service of the Massachusetts General Hospital between the years 1924 and 1930 inclusive. Of these 174 patients with 213 injuries about the elbow were treated as inpatients and have been carefully studied and followed. End result clinical and X-ray examinations have been made at a period longer than 1 year after discharge from the hospital in 140 patients with 176 elbow injuries representing 82 per cent of all the house cases. The other patients were treated in the emergency ward and out patient department of the hospital. For the most part their injuries were of less severe type so that hospital admission was not considered necessary. The records of these patients are incomplete and contain notes only of the diagnosis and treatment at the time of the first visit. These have been used chiefly for statistical purposes in order to give as complete a picture as possible of the entire problem. During the 7 year period covered by the study the total number of patients with fractures and dislocations treated in all departments of the hospital was 4,066 and the total number of skeletal injuries was 4,536 so that the fractures and dislocations of the elbow

represented approximately 10 per cent of the entire group.

A word of explanation is necessary in respect to the system of grading end results that is employed at the Massachusetts General Hospital. The result is evaluated from three standpoints: A (anatomic), F (functional) and E (economic) and is expressed by numbers ranging from 0 to 4, the former representing the minimum and the latter the maximum. Considerable latitude is permitted by the numbers: 1 representing from 0 to 25 per cent, 2 from 25 to 50 per cent, 3 from 50 to 75 per cent and 4 from 75 to 100 per cent. "Anatomic" refers to bony alignment and is determined from the X-ray. "functional" takes into consideration the range of joint motion, muscular strength and the presence or absence of pain while "economic" refers to working and earning ability. For example, A₃ F₄ E₄ means that the X-ray shows slight bony deformity but that functionally the patient is practically normal and that he is able to do the same work and earn the same wage as before injury. A₁ F₂ E₂ indicates less than 25 per cent of normal alignment, less than half of the normal motion and only about 75 per cent of the previous earning power.

Types of injury. It is important to make an accurate diagnosis of the exact type of fracture or dislocation of the elbow as the methods of treatment are different, and each carries its own particular dangers. Many of the unsatisfactory results that are seen after injuries of the elbow are the result of failure to distinguish between the different types and the attempt to treat all without distinction by one common method.

Epiphyses. The lower end of the humerus lacks a single common epiphysis similar to that at its upper end or to those at the ends of the radius, femur, and tibia. Instead, ossification proceeds from several distinct epiphyseal centers which unite with the shaft at different age periods. Any of these epiphyses, such as the capitulum or medial epicondyle,

Fig. 1. Diagram showing ossification of the epiphysis of the elbow. (From Camp and Cliley. *Am. J. Roentgenol.* 43: 277, Dec.)

may become separated as a result of trauma during the period when it is vulnerable but epiphyseal fracture of the entire lower end of the humerus almost never occurs, and no single instance of it was found in our series. A

TABLE I--GRAND SUMMARY SHEET

	House cases			Emergency ward		
	Num. ber	Per cent	Re- sults	Cases	Total	Per cent
Supracondylar	57	80.7	46	13	8	19
Medial epiphysis	4	58.5		13	36	46

Dislocations	30	1	5	63	63	71
Total injuries	213	100	151	166	166	100

knowledge of the normal X-ray appearance of the epiphyses and of the age at which they unite is essential for the proper treatment of fractures (Fig. 1).

Frequency of the various injuries. The relative frequency of the different types of fractures and dislocations about the elbow is shown in Table I. The most common injuries in order of frequency were first, dislocations; second supracondylar fractures; third, fractures of the head and neck of the radius; fourth fractures of the olecranon process.

Multiple injuries. Many of the skeletal injuries about the elbow are multiple. This is particularly true of the dislocations which are frequently accompanied by fractures and of the fractures of the olecranon, upper extremity of the radius, coronoid process, and medial epicondyle, which are often associated with other injuries either fractures or dislocations. The incidence of the complicating injuries in respect to the various fractures and dislocations of the elbow is shown in Table II.

Nerve injuries. Injury of one of the main nerves of the arm complicated the fracture or dislocation in 9, or 5 per cent of the 174 house patients. All of these injuries were of the nature either of contusions or stretching of the nerve and spontaneous recovery occurred in every instance. The various lesions are shown in Table III.

Age distribution. It may be seen from the graph (Fig. 2) that fractures and dislocations of the elbow occur with the greatest frequency among children actually 101 or 58 per cent, of the house patients were under 15 years of age. This fact should prove a stimulus to the surgeon because childhood is the most favorable age for recovery from skeletal injuries, and on that account failure to avoid functional impairment seems doubly tragic.

I. SUPRACONDYLAR FRACTURES OF THE HUMERUS

The supracondylar fractures were numerically the most frequent of the injuries in the region of the elbow and constituted 19 per cent of our group of cases. The incidence was highest in childhood, and 92 per cent of the patients were under 15 years of age, and 84 per cent below the age of 10. There seemed to

Fig. 2 All injuries of the elbow (174 house patients) Age distribution by decades.

be an extraordinary resistance to this injury in adult life judging by the absence of any instance of it between the ages of 20 and 50 years. It was re-encountered in the elderly group, and 4 of our patients were in the sixth decade (Fig. 3).

The fracture is more accurately described as diacondylar than supracondylar, but since the latter term is better known, it will be retained. The fracture line passes transversely

through the upper part of the condyles instead of above them, and in the lateral plane it slopes obliquely downward and forward. It is usually produced by a fall on the outstretched hand with backward and upward thrust on the forearm. The lower fragment is displaced backward, and the lower end of the upper fragment

TABLE II.—COMPLICATING INJURIES OF ELBOW FRACTURES

	Cases	Multiple injuries of elbow elsewhere	Fracture elsewhere
		Cases	Per cent
Supracondylar	82	2	2.4

comes to lie anteriorly and medially in close relation to the brachial vessels. Occasionally it escapes through the skin producing an open or compound fracture. In the group of patients (57) studied there were two with compound fractures or an incidence of $3\frac{1}{2}$ per cent.

The flexion type of supracondylar fracture, although rare (3 examples in 57 cases or 5 per cent) needs to be distinguished from the common hyperextension type of fracture. It generally results from a fall on the flexed elbow and the deformity is reversed the lower fragment being displaced forward instead of backward. Closed reduction is brought about by extension of the elbow. Instead of by flexion and if correction is obtained splints should be applied with the elbow in this position. The deformity is generally increased by the position of acute flexion. In the group of patients studied there were 3 examples of this type of fracture. Two were adults and one a child. Open reduction was necessary in the two former and closed reduction was satisfactory in the latter.

In the common type of supracondylar fracture when the patient is seen within a few hours of the injury reduction can generally be

accomplished by the manipulative method and the correction maintained by the position of acute flexion of the elbow. It needs to be emphasized that the position of acute flexion is not a means of reducing the fracture but of retaining alignment after reduction has been accomplished. Reduction may be performed as follows with the patient anesthetized and an assistant making countertraction on the upper arm, traction should be exerted on the forearm the elbow being extended. The elbow should be drawn downward and rotary displacement corrected. The lower fragment should then be pushed forward and the elbow slowly flexed. If the reduction is performed within a few hours of the injury before there is any vascular interference from swelling and if the replacement is complete it will be possible to bring the elbow into a position of complete hyperflexion without obstructing the radial pulse, and it should then be fixed in that position either by the application of a snug bandage or by a molded posterior plaster splint. Retention by a circular strip of adhesive plaster in our opinion is dangerous and likely to interfere with the circulation.

Ischemia. The great menace of the supracondylar fractures is much more from vascular

Fig. 4.

Fig. 5.

Fig. 6.

Fig. 6. End result one year after injury.

interruption (ischæmia and Volkmann's contraction) than from functional impairment due to faulty reduction of the fracture. Ischæmia that dreadful complication often equivalent to total loss of the arm is ever imminent and this danger must always be kept in mind. While in most instances it is a consequence of the injury rather than of the treatment and may develop in the complete absence of all constrictive dressings there is little doubt that failure to recognize it when impending and therefore to take all needful steps to prevent or check it may make a great deal of difference in respect to the amount of function that may be saved. Examination should never be confined to the region of the fracture but should include the entire extremity and tests of the circulation, cutaneous sensibility and motor power of the hand and wrist should always be made.

Absence of the radial pulse, pallor and coldness of the hand, inability to flex or extend the fingers and loss of cutaneous sensibility are the signs of fully developed ischæmia and in our opinion demand immediate operative intervention as will be described later. But it is equally necessary to recognize the signs of incomplete circulatory disturbance, and so that case to adopt a plan of treatment that will take into account both the needs of the fracture and those of the circulation as well. By these signs I refer to the presence of marked swelling about the elbow, cyanosis of the forearm and, above all, to interruption of the radial pulse

when the elbow is brought into the position of acute flexion. The radial pulse must be the guide post not only during the reduction of the fracture but also throughout the immediate after treatment and must always be carefully watched. Disappearance of the radial pulse while the elbow is being flexed following the reduction of the fracture is a sign either of incomplete reduction or of such great extravasation into the soft parts and infiltration of the tissues that the brachial artery becomes compressed as a result of the postural tension. In either case it is an indication for the return of the elbow to a position in which the radial pulsation can again be felt, and for the application of splints in that position to maintain the best alignment possible. When the circulatory balance is particularly bad it may be the part of wisdom to abandon all attempts at reduction for the moment, and instead to concentrate on improving the circulation by such measures as elevation, application of radiant heat, and even operative intervention, if indicated. After a few days when the swelling has subsided a second attempt at closed reduction may be made, or open reduction may be performed. An alternative method that has given successful results is the application of skeletal traction from an overhead frame by means of a Kirschner's wire inserted in the olecranon process. This obtains reduction of the fracture, permits the elbow to assume the position of flexion from the unsupported weight of the forearm, and

Fig 7 A. Roentgenologic appearance of malunited supracondylar fracture of humerus three months after injury. Note that ulna has taken place with the lower fragment lying posteriorly and that the lower end of the proximal fragment projects anteriorly and appears to block flexion. B. Same elbow three years later showing correction of deformity by process of growth.

at the same time secures elevation and relieves swelling.

Frank established ischemia requires immediate operative intervention. Let no one depend upon closed reduction of the fracture as a means of relieving pressure upon the vessels. Our own tragic experience with 2 patients shows the futility of this method (see Table IV). On the other hand, gratifying results were obtained in 2 patients by incision along the inner side of the elbow, evacuation of the hematoma, and by exposure and freeing of the vessels. In one case the latter were found twisted about the upper fragment and the pulsation immediately returned upon freeing them. This experience was particularly

encouraging and holds out hope that by immediate operation in the early stage Volkmann's ischemic contraction can be prevented either completely or partially. Ischemia developed in 5 of our 82 patients, or 6 per cent. Data concerning these patients is shown in Table IV.

Vascular disturbance of greater or lesser degree was present in a large proportion of the patients studied, and in these the treatment of the fracture was made secondary to safeguarding the circulation. In 22 of our 57 house patients more than one closed reduction was performed. This was usually due to the fact that the radial pulse was shut off by the position of acute flexion of the elbow and that correction could not be maintained with the elbow in a less favorable position. Open reduction was performed in 11 cases. Five of these operations were necessitated by failure of closed reduction; 1 was in a compound fracture where open reduction was combined with immediate débridement, and the 3 remaining were in patients who were admitted late, that is from 4 to 10 days after injury.

The treatment after either closed or open reduction consisted of immobilization for a period of about 3 weeks followed by protection in a sling for 1 or 2 weeks longer. No effort was made to employ early massage and movement. End result examinations were made in

TABLE IV—SUPRACONDYLAR FRACTURES WITH ISCHEMIA—FIVE CASES OR SIX PER CENT OF EIGHTY TWO CASES

Identification	Age	Time after injury	Examination of hand	Treatment	Result
C.H. (a 32412)	4	3 hrs. No previous treatment	Pallor and loss of sensation and power. Absent pulse.	Immediate closed reduction. Right angle flexion; elevation, best.	Volkmann's contraction. At F. Ex.
R.H. (W. 369947)	8	hrs. No previous treatment	Pallor, loss of sensation and power. Absent pulse.	Immediate closed reduction. Right angle flexion; elevation, best.	Volkmann's contraction. At F. Ex.
W.H. (W. 369950)	5	6 days. Radial pulse formed elsewhere and ulnar fixed in flexion.	Hand swollen, cyanotic and tender. Loss of sensation and power. Absent pulse. Elbow swollen. Forearm sore.	Split removed, elbow extended. Elevation, best. Closed reduction 10 days after injury. Right angle flexion.	Volkmann's contraction. Necrotic 3 inch above injury. End result unknown.
C.R. (W. 369308)	3	4 hrs. Two attempts at reduction made elsewhere.	Hand swollen, cyanotic and tender. Unabsorbed hematoma. Loss of sensation of lower third of arm. Faint radial pulse. Elbow swollen.	Split removed. Elbow extended and elevated. At end of 5 days closed reduction. Pulse disappeared. Incised over above vaccination of blood clot. No reduction. 140° extension.	Slight flexion contraction of wrist. Covered up with physical therapy. At F. Ex.
M.T. (E. 57479)	1	hrs. No previous treatment	Hand pale. Loss of sensation and motor power. Absent radial pulse.	Immediate operation. Medial incision; lower half skin and tissue. Exposure and freeing of vessel found twisted about upper fragment. Flap with elbow extended. Later closed reduction successful.	Pulse returned. No contraction. At F. Ex.

45 of the 57 patients more than 1 year after discharge from the hospital and the gradings are shown in Table V. The outstanding impression from their study is the excellence of the results. They were graded excellent or good meaning practically normal function in 37 or 82 per cent. There were 3 poor results, 2 due to ischaemia and 1 due to gas bacillus infection developing in a patient with a compound fracture who had been treated elsewhere and in whom disarticulation of the shoulder had to be performed immediately upon admission. Five results were graded as fair, meaning some alteration of alignment and moderate limitation of elbow function. Only 3 of these were attributed to our treatment, one being a case of ischaemia, another a patient admitted only after a delay of 10 days in whom an open reduction was done and the third the case of a patient with a compound fracture who re-fractured the elbow 7 months after the first injury.

It remains to be added that a considerable number of good and even excellent results were obtained even in the absence of complete reduction. Several patients with old malunion and uncorrected complete posterior displacement of the lower fragment have been followed in the fracture clinic and in the end obtained useful elbows. Bony consolidation always took place and although in the beginning there was an ugly deformity which seemed to block flexion of the elbow, even this

was eradicated in the course of time as growth from the lower epiphysis elongated the humerus and pushed the elbow away from proximity to the point of injury. This should be remembered when dealing with fractures associated with vascular disturbance. Change in the carrying angle of the elbow was noted in some of the end result examinations, but rarely exceeded 5 to 10 degrees, and seemed to be of little functional significance. It would seem that the alteration must be of a rather gross type if it is to constitute a handicap. The ability completely to extend the elbow was

Fig. 9, left. Posterior dislocation of elbow with fracture of medial epicondyle following reduction. Note that the epicondylar fragment has been caught in the joint space. This patient had ulnar palsy.

Fig. 10. Same case as Fig. 9 showing end-result 13 months after injury. The epicondylar fragment was removed, and the patient has recovered from the ulnar nerve lesion. There is a small area of calcification in the lateral portion of the joint capsule.

recovered in almost all cases restriction of 10 to 15 degrees being found only in a few.

II FRACTURE OF EPICONDYLES

Fracture of the medial epicondyle is common while fracture of the lateral epicondyle is rare. There were 36 patients with the former injury, or 8.2 per cent of the entire group, while there were only 7 instances of the latter injury (1.7 per cent), all insignificant and none requiring admission to the house. The difference in the frequency of the two injuries is accounted for by the difference in ossification of the two processes, the medial epicondyle having a large separate center of ossification while there is only a tiny center of ossification for the lateral epicondyle, which is well protected and does not serve as an important point of attachment for muscles or ligaments. The epiphyseal center for the medial epicondyle appears at about the ninth year and unites from the fourteenth to the fifteenth year.

Most of the fractures affecting the medial epicondyle are in reality epiphyseal separations. This is shown by the age of the patients—of the 14 patients with this injury 13 occurred between the ages of 10 and 17 years (Fig. 8).

The medial epicondyle is most commonly fractured in association with posterolateral dislocation of the elbow, being pulled away by the attachment of the strong internal lateral

ligament. This association was found in 14 of the 36 examples of this injury, or 40 per cent. The injury may be complicated by other bony injuries due to the dislocation, such as fracture of the head or neck of the radius and of the coronoid process. In the cases of fracture uncomplicated by dislocation the injury is the result either of direct violence applied to the epicondyle or of an adduction strain of the elbow.

The treatment of fractures of the medial epicondyle is chiefly the treatment of the associated injuries, that is reduction of the dislocation if present followed by fixation of the elbow in the position of acute flexion. Nothing can be accomplished in the way of direct closed reduction of the fracture, but the position of acute flexion secures relaxation of the flexor muscles of the forearm which are attached to the epicondyle and thus tends to bring about replacement.

No functional impairment need be anticipated following fracture of the epicondyle unless there is an accompanying dislocation. When the two occur in association the prognosis is that of the dislocation. In our group of 14 house patients of which 11 had associated dislocations, end result examinations were made in 11. The functional results were excellent in 10 although in 3 the epicondyle had united by fibrous union only. One result was poor but this was due to the dislocation and not to the fracture.

TABLE VI—DISLOCATION OF THE ELBOW WITH FRACTURE OF THE MEDIAL EPICONDYLE AND DISPLACEMENT INTO THE JOINT

Identification	Age	Length of time after injury	Reduction of dislocation	Ulnar palsy	Treatment	Result
W. I. I. (O 5977-1)	11	Few hours	Immediate closed reduction	Complete	Excision of fragment. Transplant of ulnar nerve	A, F, E
G. W. M. (W 110419)		1 days	Dislocation reduced by outside physician	Complete	Excision of fragment. Transplant of ulnar nerve	A, F, E
K. L. (O 48564)	16	Few hours	Immediate closed reduction	N	Immediate operative replacement of fragment	Immediate result good. Final result not known
D. A. T. (E 43119)	16	1 month	Dislocation reduced by outside physician. Had limited elbow function	Complete	Transplantation of ulnar nerve. Nothing done to fragment	A, F, E Recurrent nerve function but had limited flexion and extension of elbow
P. T. (O 455-16)	1	12 hours	Dislocation reduced by outside physician	Complete	Excision of fragment. Transplantation of ulnar nerve	A, F, E

IIA DISPLACEMENT OF THE MEDIAL EPICONDYLE INTO THE ELBOW JOINT WITH ULNAR PALSY

There is one complication that must always be looked for in patients with dislocation of the elbow and fracture of the medial epicondyle. This is displacement of the epicondylar fragment into the elbow joint and imprisonment of it there when the dislocation is reduced. The ulnar nerve being attached to the epicondyle is carried along with it into the joint and later becomes pinched between the articular surfaces when reduction of the dislocation is effected with resulting ulnar palsy. Usually the first warning of the presence of this complication is the appearance after reduction of the characteristic signs of ulnar nerve injury. An X-ray examination should be made however both before and after the reduction and in the first films the appearance of the epicondylar fragment lying widely displaced and slightly to the outer side of the medial ridge of the trochlea should lead one to anticipate its occurrence while in the postreduction films the interarticular position of the fragment is clearly shown (Figs 9 and 10).

The treatment of the condition necessitates immediate operation to remove or replace the fragment and to free the nerve. The longer the nerve is compressed the greater the time that will be required for its recovery. Occasionally ulnar palsy is absent, but even then the intra-articular fragment should be removed as it will interfere with elbow function. In our opinion it is preferable to excise rather than to replace the fragment as this elimi-

nates the problem of fracture healing and the patient may be treated as for an uncomplicated dislocation alone. If the fragment is removed it is advisable to transplant the nerve to the front of the elbow for the sake of safety. Excision of the fragment causes no functional impairment.

In our group of 14 patients with fracture of the medial epicondyle associated with dislocation of the elbow the epicondylar fragment was caught in the joint after the reduction in 5 instances. In 4 of the 5 cases there was complete ulnar palsy. The treatment and results are shown in Table VI.

III FRACTURES OF THE CONDYLES OF THE HUMERUS

The group of the condylar fractures includes fractures of the medial and lateral condyles and the intercondylar or so-called T fractures. The fractures of the single condyles are usually oblique splits extending downward from the lateral or medial supracondylar ridge respectively into the trochlear or capitellar

TABLE VII—FRACTURE OF THE CONDYLES OF THE HUMERUS

The group of condylar fractures comprised 50 cases divided as follows:

	House cases	F. B. cases
Internal condyle	5	12
External condyle	1	14
Intercondylar	12	2

Internal Condyle

Identification	Age	Period after injury	Complications	Displacement	Treatment	Result
H.B. (E. 36640)	19	Few hours	None	++++	Closed reduction unsuccessful. Open operation performed with excision of condyle	No P.D. A poor result
H.M. (E. 3664157)		Few hours	None	++++	Closed reduction with fixation at right angle failed. Second closed reduction performed later with fixation of elbow in acute flexion	A.P.R.E. Right luxation of elbow
A.P. (O. 27 846)	34	Few hours	None	++++	Closed reduction unsuccessful. Open reduction performed with fixation of fragment by steel screw	A.P.R.E. Right luxation of elbow
C.H.A. (O. 285)	18	Few hours	Recent operation for contracture	+++	Closed reduction performed with fixation of elbow in acute flexion. Malunion began at end of 4 days	Immediate result good. No end-result
J.A.M. (E. 300784)	66	Few hours	Diabetes. Fracture of patella and carpal scaphoid	++	Reduction not considered necessary. Fixation with steel wire. Early massage and mobilization	Immediate result good. End result not obtained

External Condyle

A.C. (O. 158031)		Few hours	None	+	No reduction. Fixed in acute flexion	A.P.R.E.
S.M. (O. 1580115)	66	Few hours	None	+	No reduction. Fixed in acute flexion	A.P.R.E.
P.K. (O. 267 112)	18	Few hours	None	++	Closed reduction unsuccessful. Open reduction performed, no lateral fixation. Elbow fixed in acute flexion	A.P.R.E.
A.S. (O. 1003317)	37	Few hours	Fracture of tibia	++	Closed reduction performed and elbow fixed in acute flexion for 4 days. At the end of 6 months very little motion of elbow. Operation reduction of lateral condyle	A.P.R.E. Flexion 120° Extension 120° An industrial compensation case
M.P. (O. 1049117)	8	Few hours	Posterior dislocation of elbow	+++	Closed reduction performed. Elbow fixed in acute flexion	A.P.R.E.
P.H. (O. 27 384)	16	Few hours	Wound over olecranon, not compound	+	Debridement of wound. Closed reduction performed with fixation of elbow in acute flexion	Immediate result good. End result not obtained

TABLE IX.—FRACTURES OF THE CONDYLES OF THE HUMERUS (INTRA ARTICULAR)

Intercondylar (T) Fractures

Identification	Age	Period after injury	Complications	Displacement	Treatment	Result
H.M.W. (O 39113)	12	Few hours	Fracture external malunion	++++	Closed reduction, traction and suspension with elbow in right angle flexion. Poor position	AsFsEs About 1/2 limitation of motion
G.M.A. (E 279227)	18	Few hours	Primary injury of radial nerve. Later recovered spontaneously	++++	Closed reduction unsuccessful. Operative reduction with fixation of condyles by screw. About 1/2 limitation of motion	AsFsEs
A.B. (W. 261819)	20	Few hours	Old ununited fracture of capitulum	+++	Closed reduction attempted on three different occasions without success. Later open reduction performed with fair position but resulted in ankylosis. Excision of elbow performed later	AsFsEs Fair motion but elbow is weak and unstable
E.J. (E. 285921)	15	Few hours	Compound and badly soiled	++++	Debridement performed with excision of the condyles. Fixation in traction and suspension with elbow at right angle	AsFsEs Excellent motion but elbow is weaker than normal
T.J.L. (O 307780)	20	1 year	Ununited fracture	++++	Compound fracture treated by outside physician with failure of union. On account of age no operation advised. Brace fitted	AsFsEs Patient died 15 mos. later
G.D. (E. 21111)	11	Few hours	Old infantile palsy on affecting arm	++	Closed reduction performed and elbow fixed in acute flexion	AsFsEs
L.Z. (E. 134030)	14	Few hours	Fracture of head of radius	++++	Treated by traction and suspension with elbow in different positions for 3 weeks	AsFsEs
L.R. (W. 255773)	8	24 hours	Fracture of lower end of radius	++	Closed reduction. Elbow fixed in acute flexion	AsFsEs
L.D. (W. 216413)	14	Few hours	None	++++	Closed reduction unsuccessful. Open reduction performed with fixation of condyles by screw	AsFsEs Moderate limitation of extension
F.W. (E. 261114)	40	Few hours	None	++	Closed reduction. Elbow fixed in acute flexion	AsFsEs
E.P. (W. 217411)	10	1 day	Scarlet fever	++	Closed reduction performed twice elbow fixed in acute flexion	AsFsEs
P.O. (E. 205477)	15	Few hours	Febrile-minded. Post operative infection	++	Open reduction performed 4 days after injury. Fixation with 2 plates and screws. Developed abscess but no osteomyelitis. Healed after removal of plates	AsFsEs Slight limitation of extension

portions of the articular surface of the humerus. The intercondylar fractures are often of the T or Y type—that is a transverse fracture through the shaft of the humerus at its junction with the condyles combined with a vertical split down between the condyles. These are often accompanied by comminution of greater or lesser extent (Fig. 11).

The condylar fractures are severe injuries and seriously menace the future function of the elbow joint. Extensive pathological changes are produced in the articular surfaces and joint capsule both as a result of the injury and of the reparative process. The displacement on the one hand may be of an extreme type with separation and rotation of the condyles and overriding of the shaft fragment, or on the other may be almost completely absent. Between these extremes all degrees of

displacement may be found. Because of this variation the treatment of condylar fractures is always an individual problem and must be decided after consideration of the nature of the fracture, the extent of the displacement, and the age of the patient.

Our group of condylar fractures comprised 50 cases (11 per cent of the entire group) divided as shown in Table VII. The salient facts about the individual patients are shown in Tables VIII and IX.

It will be noted that a little more than half of the patients (54 per cent) were treated in the Emergency Ward only. All of these were fractures with little or no deformity for whom house admission was not considered necessary. In view of the prevalent impression of the invariable severity of condylar fractures it is a matter of interest to have found among them

Fig. 1. Fractures of the condyles of the humerus (50 cases). Age distribution by decades.

such a high proportion of injuries that appeared to have but slight functional significance. Such injuries occurred chiefly in the first two decades of life while the fractures with deformity reached their peak in the age group between 30 and 40 years.

End result examinations were obtained in 20 of the 23 house cases, and the gradings are shown in Table X. From an analysis of these cases the following conclusions seem justified:

1. The method of closed reduction is of value in the condylar fractures with slight or moderate deformity but is not effective in the comminuted fractures with severe deformity, especially those of the intercondylar type.

2. In condylar fractures with severe deformity the choice would appear to lie between

open reduction preferably with internal fixation of the major fragments by screws or plate or treatment in suspension and traction with early mobilization of the elbow joint. The decision between these methods should take into consideration the patient's age, occupation and general condition and the facilities available for performing technically difficult and potentially dangerous operations upon the bones and joints.

3. Following closed reduction of fractures of the medial condyle, retention of position is favored by the position of acute flexion which secures relaxation of the muscles attached to the condylar fragment. For the same reason in fractures of the lateral condyle the position of complete extension is the more favorable.

TABLE X.—END RESULTS (1 YEAR) AFTER CONDYLAR FRACTURES (INTRA-ARTICULARLY)

Method of Treatment	Results

Immediate results good.

Fig. 13 left Fracture of capitellar epiphysis with small plaque of bone attached. There is moderate rotary displacement. The normal elbow is shown for comparison.

Fig. 14. Same case as shown in Fig. 13 showing end result two years after injury. The capitellar epiphysis was replaced by open operation and sutured. There was no arrest of growth.

4 Following open reduction early mobilization is to be urged and this is facilitated by secure internal fixation of the fragments. Postoperative support is best provided by the application of traction and suspension apparatus. This protects the elbow and also permits mobilization.

5 Skeletal traction by means of a wire (Kirschner) passed through the olecranon may prove of value in the treatment of comminuted fractures of the condyles with deformity but was not used in any of these patients. It offers a means of securing continuous extension in the axis of the humerus while at the same time permitting the elbow joint to be maintained in the position of right angle flexion.

6 Excision of the condyles should not be performed except immediately in certain badly soiled compound fractures as a step in the operation of débridement or late in case of complete ankylosis of the elbow. In the latter condition arthroplasty is preferable to excision and results in a more stable joint.

IV FRACTURES OF THE CAPITELLUM

Two types of injury affecting the capitellum must be distinguished first those involving the epiphysis which occur only in children below the age of 15 and second those involving the capitellar portion of the articular surface in adults. Both are serious injuries but the epiphyseal fracture is the more common and therefore the more important of the two injuries.

IV A FRACTURE OF THE CAPITELLAR EPIPHYSIS

Of the epiphyseal fractures one must distinguish between those with incomplete and those with complete displacement.

Incomplete displacement. Many fractures of the capitellar epiphysis are associated with such slight displacement that there is failure to recognize the nature of the injury even upon X ray examination. The patient is dismissed with a diagnosis of sprain or confusion. Adequate protection of the elbow is not provided and it is only later when continued irritation has resulted in persistent pain and stiffness that a correct diagnosis is made.

In order to recognize pathological variations it is important to know the normal anatomic features. In the lateral roentgenogram the osseous center of the capitellar epiphysis projects forward and downward from the humeral shaft and gives an appearance somewhat similar to that of a hockey stick with a shortened head. The anterior surface of the epiphysis forms a continuous line with that of the humeral shaft except for the interruption in the shadow due to the cartilaginous plate. In the fractures with incomplete displacement the epiphysis is displaced somewhat posteriorly and there is a distinct jog in the line of the anterior surface. The roentgenogram must be made with the tube accurately centered so as to produce a true lateral view or this slight displacement will not be recognized. The anteroposterior view fails to show any abnormality the fracture line being invisible since it coincides with the cartilaginous disk.

Fig. 15. Capitellar epiphysis fractures (11 cases). Age distribution.

Epiphyseal fracture should be suspected in any child who presents objective signs of injury to the elbow such as pain, swelling, tenderness, and limitation of motion, yet whose roentgenograms at first glance fail to show any evidence of bony injury. The relations of the capitellar epiphysis to the humeral shaft should be scrutinized closely in such cases and a second X-ray examination should be made if any doubt exists as to one of the views being a true lateral one. Films should also be made of the uninjured elbow for purposes of comparison with the normal.

The injury is not of great importance when treated properly. It is unnecessary to correct the displacement, as a rule, as this is too slight to cause any functional disturbance. Exceptions to this rule, however, must be recognized. Fixation of the elbow is, however, necessary preferably in the position of acute flexion. This should be maintained for a period of 2 to 3 weeks following which mobilization may be begun.

Complete rotary displacement. Fracture of the capitellar epiphysis with complete rotary displacement is a distinct clinical entity which has not heretofore received adequate recognition. The mechanism of the injury is apparently a medial or varus deviation of the forearm from indirect violence throwing strain upon the lateral ligament of the elbow which in turn pulls off the capitellar epiphysis, usually with a thin layer of bone attached to the cartilaginous plate. The epiphysis is displaced outward and rotated upside down by the pull of the extensor muscles attached to its lateral surface (Figs. 13, 14).

There is complete loss of contact between the fractured surfaces and failure of union is bound to result unless replacement is secured. This can be accomplished with certainty only by the open method and in our opinion no

other form of treatment should be attempted. Open reduction is easy when performed early; the epiphysis can be fitted back into position and secured by one or two chromic gut sutures passed through the ligamentous attachments and periosteum. Following operation the elbow should be splinted in the position of right angle flexion or partial extension to secure relaxation of the extensor muscles of the fingers and wrist.

Several children with ununited fracture of the capitellar epiphysis have been followed on the fracture service of the Massachusetts General Hospital, and the end results of the same condition have also been seen in adults. There is increasing deformity of the lower end of the humerus over a period of years due to absence of growth from the capitellar epiphysis. The medial side of the humerus outgrows the lateral side and there develops marked cubitus valgus deformity. This not infrequently causes elongation or stretching of the ulnar nerve with late or delayed ulnar palsy, sometimes not coming on until 15 to 20 years after injury. The loose fragment displaces in and out of the elbow joint on movement, and although a fair range of motion is retained, there is instability and loss of power. In patients with ununited fractures of the capitulum who are seen within 3 to 4 years after injury improvement can be obtained by an operation designed to bring about union between the loose fragment and the shaft with the aid of a bone graft, and the benefits of surgical treatment even at this stage should be more generally recognized.

In our group of elbow fractures there were 11 instances of epiphyseal fracture of the capitellum. The ages of the patients varied from 3 years to 13 years but the peak of the incidence was at the sixth year (Fig. 15). The types of epiphyseal injury that were

TABLE XI.—EPIPHYSEAL FRACTURES OF THE CAPITELLUM

Identification	Age	Age of Injury	Displacement	Treatment	Result			
					A	F	E	
Fractures with Slight Displacement

J.L. (O.263333)	11	Fresh	++++	Closed reduction attempted but was unsuccessful. Open reduction was performed and good position obtained	3	4	4	Excellent
G.R. (E.291815)	6	7 days	++++	Open reduction was performed with complete replacement. Elbow fixed in acute flexion	4	4	4	Excellent
R.W. (E.291774)	6	3 days	+++	Closed reduction attempted but was unsuccessful. Open reduction was performed with complete replacement. Fixed in acute flexion				End-result not obtained. Immediate result good
M.D. (O.286 50)	3	Fresh	+++	Open reduction was performed with complete replacement. Fixed in acute flexion				End-result not obtained. Immediate result excellent
L.P. (O.291418)	5	4 years	Non-union of epiphysis	Open operation was performed. Old fractured surfaces were freshened. Bone graft was interposed between fragments to restore normal articular plane. Fragments fixed with 2 steel screws. Elbow fixed by posterior plaster splint in right angle flexion	3	4	4	Good
Complete Epiphyseal Fractures with Lateral Displacement but No Rotation								
J.S. (E.262454)	5	Fresh	++	Closed reductions were performed twice with fixation of the elbow in acute flexion but with little improvement. Patient developed intractable, making operative or further attempts at reduction useless	3	4	4	Excellent
F.L. (O.270296)	8	10 days	Post-lat. dislocation of elbow	Atypical lateral rotation of epiphysis. Open reduction was performed with secure of fragment. Excellent position was obtained	4	4	4	Excellent
B.P. (O.297582)	6	25 days	Fracture already united	Considerable deformity. Epiphysis was displaced outward but not rotated. Open reduction was considered but rejected. Active use was advised				End-result not obtained

encountered together with the methods of treatment employed, and the end results so far as they are known, are shown in Table XI. No instances of arrest of growth were encountered and this is due to the fact that the fracture line passes proximal to the epiphyseal plate instead of through it.

IVB FRACTURES OF THE CAPITELLUM (ADULTS)

Fracture of the capitellum in the adult usually takes the form of a separation of a portion of the articular surface with forward and upward displacement of the loose fragment and the formation of a free body in the joint. Occasionally the fracture is of the compression type, the articular surface being driven upward and impacted into the under

lying bone. The fracture is apparently produced by force transmitted upward through the radius, the head being driven against the articular surface of the capitellum. The fracture is frequently associated with other injuries in the region of the elbow such as fracture of the head of the radius or dislocation of the ulna on the humerus. The treatment depends entirely upon consideration of the individual case. When a loose fragment has been separated, it may be necessary to remove this by open operation, in other types of fracture open reduction may be indicated. It is generally impossible to influence the deformity by closed methods.

There were 3 instances of this fracture in our group of 439 elbow injuries the ages of

Fig. 16 Upper end of radius fractures (75 cases) Age distribution by decades.

the patients being 42, 51 and 69 years respectively. In one case the fracture was complicated by posterior dislocation of the elbow this was reduced and the result at the end of 1 year was graded A, F, E₃. In the second case there was an accompanying fracture of the olecranon process. This was treated by operative suture with wire. The patient later died of coronary thrombosis. The third patient was only admitted 4 months after injury at which time there was a bony ankylosis of the elbow. Arthroplasty was performed with the insertion of a free flap of fascia lata, and at the end of 1 year the result was graded A, F, E₃. There was a nearly normal range of motion but some instability and loss of power

elbow they constituted the third largest group of elbow injuries. The accompanying graph (Fig. 16) showing the age incidence of the fracture indicates that it is more commonly an injury of adult life than of childhood and that the peak is reached in the age group between 20 and 40 years.

The injury may be produced either by indirect violence the force being transmitted along the shaft of the radius and driving the head against the capitellum or by direct violence acting on the lateral aspect of the upper forearm or elbow. In a fairly high proportion of the cases (27 per cent in our series) the fracture occurs in association with some other injury of the elbow particularly postero-medial dislocation of the elbow or fracture of the olecranon process. This shows the vulnerability of the head to articular displacements of any kind. The list of complicating injuries is shown in Table XII.

Several different types of fracture of the radial head can be distinguished and their

V FRACTURES OF THE HEAD AND NECK OF THE RADIUS

Fractures of the head and neck of the radius numbered 75 cases, or 17 per cent of the entire group. After the supracondylar fractures of the humerus and the dislocations of the

Compound fractures	3	

differentiation is important from the view point of treatment. The list of these together with their incidence in our group of 30 carefully studied house patients is shown in Table VIII.

The epiphyseal fractures numbered 3, or 10 per cent in our group of 30 house patients. Two of the patients were aged 8 years and one 13 years. Below the age of 7 years the epiphysis is largely cartilaginous and able to resist injury and it unites with the shaft at the age of 14 to 15 years so that the age period in which epiphyseal fracture may be produced is relatively short. The osseous center represents only a thin disk of bone and corresponds to the radial head. When the epiphysis is fractured and displaced it is quite likely to become isolated as a loose body in the joint, devoid of blood supply. This occurred in one of our 3 patients when no operation was performed to replace the epiphysis. In the other patients open reduction was performed and consolidation in good position was obtained (Fig. 17). No method of internal fixation was employed, the fragment being retained in alignment by the position of acute flexion of the elbow. Obliteration of the epiphyseal cartilage occurred in both cases but no appreciable shortening of the radius resulted since the amount of growth contributed by the upper epiphysis at this age is slight. Table XIV presents summaries of the records of the patients with epiphyseal fracture.

Fractures of the head and neck of the radius, if associated with displacement, commonly cause serious impairment of elbow joint function. Not only does the bony deformity limit or prevent rotation of the upper articular

Fig. 17 Epiphyseal fracture of the upper end of radius. A. Roentgen appearance on admission showing tilting of the head. B. Following open reduction. C. Two months later showing union.

element in the lesser sigmoid cavity of the ulna with loss of the ability to pronate and supinate the forearm but there is frequently limitation of extension of the elbow as well. This is due to scar formation and thickening in the anterior capsular ligament usually the result of the displacement of a fragment of bone in this direction. To prevent future disability it is necessary to correct the bony deformity but the situation and nature of the fracture are such as to render it impossible except by open operation. This may take the form of open reduction, excision of the displaced fragments or resection of the entire radial head. When the bony deformity is absent or slight, no impairment of function should follow, and the only treatment indicated is protective splinting for a period of 2 to 3 weeks with gentle daily mobilization.

TABLE XIV—EPIPHYSEAL FRACTURES UPPER END OF RADIUS

Identification	Age	Age of injury	Complications	Displacement	Treatment	Result (year)			
						A	P	E	
R. E. (W. 566360)	13	3 days	Fracture of olecranon without displacement	Marked +++	Open reduction performed 8 days after injury. No internal fixation. Elbow splinted in acute flexion.	4	4	4	Epiphysis closed
M. E. (W. 57663)	8	6 days	Fracture of olecranon without displacement. Fertilized	Mild +++	Elbow fixed in slight right angle flexion. Reduction not attempted.	3	3	3	Separation lacks 5° or less; flexion lacks 20°. Loose body in joint
L. P. (O. 576728)	8	14 days	Greenstick fracture of ulna	Marked +++ Callus present	Open reduction performed. Fragment loosened and replaced. Held in position by fixation of elbow in position of acute flexion.	3	3	4	Only about 20° rotation of forearm. Flexion and extension normal.

Excision of head—Early	2	1	1	0	
Late	4	1			
Total	30	5	2	1	6

In our group of 30 house patients with fracture of the head and neck of the radius operative treatment was employed in 20. The end results in these cases are shown in Table XV. In grading these results the term good was used to designate 75 per cent or better restoration of pronation and supination and of flexion and extension.

Following the study of these cases and an analysis of the end results it seemed fair to draw the following conclusions in respect of treatment:

1. Open reduction ought not to be attempted except in the case of epiphyseal fractures and occasionally in fractures of the radial neck.

2. Excision of loose bone fragments should be performed only in the case of fractures involving the radial head when there is a single fragment and when at least two-thirds of the circumference of the head remains in tact including the inner half that articulates with the ulna.

3. In all comminuted and displaced fractures of the head and neck resection of the head should be advised.

4. Better results are obtained when resection is performed early (within the first 2 weeks) rather than late.

5. A common complication is ossifying hematomas or myositis, particularly in fractures associated with dislocation of the elbow. This may follow resection of the radial head but is not necessarily the result of operation.

6. To guard against this complication at the time of operation it is necessary to obtain

careful hemostasis and to avoid leaving behind any loose bone fragments. (This is a common error.)

7. Following the excision of a single fragment or the resection of the radial head the elbow should be splinted in the position of right angle flexion for the period of 1 week, following which mobilization should be begun.

8. Fracture of the head or neck of the radius is a serious injury and while the prognosis is good for the recovery of an useful elbow rarely is it a normal elbow. On the whole the results in this group of injuries were less good than in any other type of fracture or dislocation of the elbow.

VI. FRACTURES OF THE OLECRANON

Fractures of the olecranon constituted the fourth largest group of the injuries of the elbow and numbered 61 or 14 per cent of the entire group. Of these 33 were treated in the hospital as in patients, while 28 were treated as out patients. For the most part these latter represented incomplete fractures or fractures without displacement. They have been used chiefly for statistical purposes. End-result notes (1 year or more after discharge) are available on 25 of the 33 house patients, or in 75 per cent.

The age distribution of the fracture as shown by the accompanying graph (Fig. 18) is fairly even throughout the various decades, but with the peak in the first three.

The injury may be produced by a fall on the outstretched hand the elbow being in a position of semi-extension, or in rare instances, by direct violence, as from a fall on the flexed elbow or a direct blow. The former is the common mechanism, the olecranon giving way and fracturing as a result of the forcible flexion of the elbow against the resistance of the triceps muscle. In this type of injury the fracture is generally transverse but there may be one or two small fragments in addition to the main ones. The olecranon fragment is generally retracted and separated from the rest of the ulna by the pull of the triceps, especially when the elbow is flexed. Separation of the fragments depends, however upon the extent of laceration of the lateral aponeuroses of the triceps tendon which blend with the fascia of

Fig. 18 Olecranon fractures (61 cases) Age distribution by decades

the forearm and provide a second point of insertion for the triceps muscle. When these are intact they limit or prevent displacement. Direct violence tends to produce a comminuted type of fracture and the rarity of this mechanism is shown by the fact that only one example of this was found in 33 fractures. Separation of the fragments sufficient to necessitate operative repair was present in 24 cases, it was slight in 3 and absent in 4.

Complicating bony injuries were present in 14, or 47 per cent of the cases and of these 9 or 27 per cent represented other injuries in the region of the elbow. Fractures of the head or neck of the radius were most common and occurred in 6 or 18 per cent of the patients.

The treatment of olecranon fractures depends chiefly upon the amount of displacement that is present. Fractures without separation may be splinted with the elbow in the right angle position for a period of about 3 weeks but the splints may be removed every day for physical therapy and mobilizing exercises. When the separation is slight good contact between the fragments can usually be brought about by complete extension of the elbow. The reduction should be verified by X ray examination, and when the position is shown to be satisfactory the elbow should be immobilized in this position. Mobilizing exercises should not be started until the end of 3 weeks. When gross separation of the fragments is present we believe that open reduction and suture is the best method of treatment. It has the advantages of securing close approximation of the fragments, of removing

interposing tendinous fibers which interfere with bony consolidation and of securing bony, instead of fibrous union. Operative repair when properly carried out shortens the period of convalescence and obviates the necessity of prolonged fixation of the elbow. It should be remembered however that it exposes the patient to the risk of infection, and that this hazard can be overcome only by skilful surgery and meticulous technique.

We believe that operative repair should bring about such close and firm fixation of the fragments that there should be no need for external splinting, or at the most for splinting of short duration only. Prolonged postoperative fixation with the elbow in extension always results in slow recovery of function and should be avoided. Kangaroo tendon and chromic catgut are inadequate as suture materials and do not provide the secure fixation of the fragments necessary for early mobilization. We have seen several instances of secondary displacement following operation when these materials have been used. Metallic wire, steel screws, or flanged nails may be used successfully for this purpose but for a number of years we have been partisan of the use of living fascia lata suture—a method that has been developed and used extensively by the surgeons of the fracture service of the Massachusetts General Hospital for the treatment both of fractures of the olecranon and of the patella. A fascial strip one half to three quarters of an inch in width is passed through holes one-quarter of an inch in diameter drilled in both fragments, the ends are tied,

and the knot made secure by transection with interrupted sutures of fine silk. Such fascial sutures live and do not constitute foreign bodies. On account of their great tensile strength they secure firm fixation and the elbow may be flexed to the right angle without danger of separating the fragments. No splinting is required beyond the use of large soft dressings. Active motion may be begun at the end of 1 week, and the function is quickly regained. A second method of fascial reinforcement that was tried consisted in suturing the fragments with kangaroo tendon and then laying a free flap of fascia lata over the fracture line on the posterior surface and suturing it to the triceps tendon and adjacent soft tissues. This method seemed less good than the other.

The results 1 year or more after injury obtained by the various types of treatment in our group of 33 patients are shown in Table XVI. It is gratifying to note that in 21 of the 25 patients (84 per cent) these were graded as excellent or good. Of the 10 patients treated

without operation 4 had fractures without displacement and the elbow was fixed only by a sling in 3 the separation was slight and the arm was splinted with the elbow in extension in 2 the elbow was suspended in right angle flexion from an overhead frame. Of the latter 2 patients one had a comminuted fracture without separation and the other an uninfected compound fracture without much displacement. One other patient with an accompanying fracture of the head of the radius was admitted to the hospital 4 months after injury. The head of the radius was excised but the fractured olecranon had healed and did not require treatment.

Open reduction was performed in 23 patients, but 3 operations were required in 1 case so that there was a total of 25 operations. There were 2 postoperative infections, one severe and resulting in ankylosis, the other minor and leading to no functional impairment. The three poor results were caused first by postoperative sepsis leading to ankylosis second by a complicating fracture of the head of the radius the functional impairment here probably being accounted for by this rather than by the fracture of the olecranon and third, by a failure to secure good approximation of the fragments by fascial suture. The latter patient was discharged with what was considered satisfactory although not perfect reduction of his fracture. He drifted into other hands, and 5 months later underwent a second operation on the elbow. When examined at the end of 1 year it was found that the olecranon had been removed, there was a complete ulnar nerve palsy and the patient had considerable functional impairment of the elbow. It is fair to question whether this patient would not have had a better result if he had been left alone. One patient with an ununited fracture of the olecranon of 3 months duration required three operations. At the first the fragments were freshened and sutured with kangaroo tendon but the post-operative X rays showed the fragments had re-separated. A second operation was performed 10 days later and the fragments were fixed with wire. Consolidation was obtained with good function but 5 months later re-fracture occurred as a result of a fall. A third

Fig 19. Anterior dislocation of head of radius associated with fracture of shaft of ulna. A and B The deformity at the time of admission. C and D Appearance following open reduction of the head of the radius.

operation was performed and the fragments were sutured with wire and fascia lata. The result at the end of 1 year was graded A, F, E. There were no other instances of refracture. There were 3 compound fractures and in 2 immediate débridement was performed with suture of the lateral expansions of the triceps. Both of these wounds remained clean, and the reduction of the fracture was satisfactory, but the end results are unknown. The third patient was admitted 5 days after injury and the wound a pin point opening remained clean.

It may be said in conclusion that

1 The results of fracture of the olecranon process are in general excellent.

2 The fracture is complicated in about 25 per cent of the cases by other injuries of the elbow and of these the most frequent are fractures of the head or neck of the radius. Such complicating injuries when present modify considerably the prognosis of fracture of the olecranon.

3 Fractures with little or no displacement may be treated with the elbow splinted in extension or supported in a sling at right angle flexion. They may be treated by early massage and mobilization.

4 Fractures with separation should be subjected if possible to operative repair with firm fixation of the fragments by wire screw or fascial suture. Internal fixation should be

secure enough to obviate the necessity of external splinting and to permit active mobilization at the end of one week.

VII FRACTURE OF THE CORONOID PROCESS

In the group of 174 house patients with elbow injuries there were 7 instances of fracture of the coronoid process of the ulna. All of the patients were adult, 2 being in the third decade, 1 in the fourth and 4 in the sixth. Six of the 7 fractures occurred as complications of dislocation of the elbow, and of these 4 were also associated with fracture of the head or neck of the radius and 2 with fracture of the medial epicondyle. In the seventh patient the fracture of the coronoid complicated a fracture of the olecranon process.

The fracture is apparently caused by posterior displacement of the ulna upon the humeral condyles, the projecting tip of the process being knocked off. The small fragment may be retracted upward by the pull of the brachialis anticus muscle but in our group of patients the amount of separation was never great. Healing may take place by fibrous instead of bony consolidation but this of itself ought not to result in any functional impairment. The particular menace of fracture of the coronoid however, lies in the danger of ossification of the hematoma that develops in the region of the fracture and of the anterior capsule. This complication occurred in one of

Fig. 20 Dislocations of the elbow (93 cases) Age distribution by decades

our patients following an operation for an old unreduced dislocation of the elbow. An ossifying hematoma developed and resulted in complete bony ankylosis. We are inclined to feel that this resulted from the operation rather than from the accompanying fracture of the coronoid process. In general fracture of the coronoid rarely needs to be considered from the standpoint of treatment and all attention may be focused on the treatment of the accompanying dislocation or fractures.

Of the 7 patients 3 were treated by reduction of the dislocation and fixation in acute or right angle flexion 2 with fractures of the head and neck of the radius underwent operation for excision of the head of the latter bone. In one of these cases the tip of the coronoid was also excised and this patient obtained a good result. One patient with an accompanying fracture of the olecranon process was treated by operative suture of the ulnar fragments. The results at the end of 1 year were graded as excellent in 3, good in 1, poor in 2 and unknown in 1. Both of the poor results were to be attributed to the accompanying fractures or dislocation rather than to the fracture of the coronoid process.

VIII. DISLOCATION OF THE UPPER END OF THE RADIUS

In the group of 439 elbow injuries there were only 3 instances of isolated dislocation of the

radial head and in all of these the displacement was in the anterior direction. In all 3 patients there was an accompanying fracture of the shaft of the ulna, and in 1 there was a fracture of the olecranon as well. The fracture of the ulna was compound in one instance. The ages of the patients were 8, 17 and 28 years respectively. The trauma was a blow or fall on the extensor surface of the forearm.

The radial head is retained in its articulating position with the lesser sigmoid cavity of the ulna by the orbicular ligament, and as long as the ulna remains intact the interosseous membrane also constitutes a strong retaining ligament. For these reasons anterior dislocation is almost invariably accompanied by a fracture of the shaft of the ulna, either in the upper or middle thirds. This association is so definite that whenever a displaced fracture of the ulnar shaft is seen without accompanying fracture of the radius, an X-ray examination should be made of the elbow and a dislocation of the upper end of the radius looked for.

Treatment of the dislocation should take into consideration that either the orbicular ligament has been ruptured in which case operative repair is indicated or that the head has escaped from under the ligament in which case replacement can be accomplished only by operative exposure. Furthermore the relation of the dislocation to the fracture of the ulnar shaft must be borne in mind and reduction of the ulnar deformity must be accomplished simultaneously with that of the dislocation. Open reduction of the dislocation should be performed through an anterior incision after preliminary exposure and isolation of the radial nerve. After replacement of the dislocated bone the orbicular ligament should be sutured and the fracture of the ulna reduced by open operation and plating if neces-

TABLE XVII—ANTERIOR DISLOCATION OF RADIAL HEAD

sary. The best position for retention is with the elbow in acute flexion and with the fore arm supinated in order to relax the pull of the biceps muscle. Mobilization of the radius in pronation and supination may be started at the end of 7 to 10 days but the fracture of the ulna requires protection for from 3 to 4 weeks.

It has been claimed that reduction of the radial head is unnecessary for good function but this is not borne out by our own observations. Instability of the head of the radius results and may be painful but in any case is associated with weakness that makes heavy work impossible.

The histories of our 3 patients together with the end results are shown in Table XVIII.

IX. DISLOCATION OF BOTH BONES AT THE ELBOW

During the 7 year period under study our records showed 93 patients with dislocations of the elbow. They constituted the largest class of all the elbow injuries exceeding even the supracondylar fractures and represented 20 per cent of the entire group. The age distribution is shown in Figure 20. The peak of the incidence is found in the first two decades and 59 per cent of all the dislocations occurred in this period. There is a marked drop in the incidence in the later decades.

Complicating fractures in the region of the elbow were very common and were found in 53 patients or 59 per cent. The list of injuries associated with elbow dislocations in the 30 carefully studied house patients is shown in Table XVIII. From a study of these multiple injuries, it appears that complicating fractures are rare with dislocations in the first decade when the ends of the bones are largely cartilaginous. In the second decade they are common due chiefly to the vulnerability of the epiphysis for the medial epicondyle during this period. They are rare again in the third decade but after that dislocation is commonly accompanied by a fracture of one of the bony elements—the upper end of the radius, the coronoid process, external condyle or capitellum.

Dislocation of both bones at the elbow may take place in the posterior, medial lateral, or anterior directions, that is the ulna carrying

Epiphyseal fracture lower end of radius	1	

with it the radius may displace from the humerus in any of these directions. We believe it is preferable and more in accord with usage in dislocations elsewhere to describe the dislocation in this manner rather than to observe the traditional method which treats the ulna as the fixed point and designates the type of dislocation according to the direction of the displacement of the humerus. In the group of 30 house patients with dislocations the displacement was found to be posterolateral in 10 directly posterior in 11 posteromedial in 5 lateral in 3 and undetermined in 1. Thus posterior displacement of one or another type was present in 26 of the 30 patients. There were no instances of anterior dislocation and this type usually associated with fracture of the olecranon is known to be very rare. In respect to the mechanism of the injury it was impossible to determine the number in which the dislocation was caused by direct violence from a blow or fall on the elbow or in which it resulted from a fall on the outstretched hand. The latter mechanism appeared more common.

From the standpoint of treatment the first and most important requirement is to make an exact diagnosis of the nature of the injury. This ought to be fairly obvious from local examination, but an X ray examination should

Fig. 31. Posterior dislocation of the elbow associated with fracture of the head of the radius. A. Appearance of deformity at time of admission. B. Following reduction of the dislocation. The radial head is still displaced. C. Following exclusion of the head of the radius.

always be made to confirm it and to reveal any accompanying fracture that may be present. In spite of this long established rule there were included in the group 6 patients with late unreduced dislocations varying from 28 days to 5 months after injury in which a correct diagnosis had never been made.

Dislocation of the elbow whether or not complicated by fracture requires immediate reduction. Closed reduction becomes increasingly difficult with the lapse of time, and the earlier it is performed the easier it is to accomplish and the less the danger of damaging any of the joint structures. The patient should be anesthetized in order to obtain complete muscular relaxation and to permit of reduction without the use of excessive force. The elbow should be hyperextended to unlock the coronoid process from the olecranon fossa, and while an assistant exerts gentle traction on the wrist, the operator should apply both thumbs to the olecranon and press the olecranon forward. When the ulna lies in a medial or lateral relation to the humerus it should first be pressed into a directly posterior relationship and then reduced. When reduction is accomplished the elbow should be flexed to make the reduction secure, and fixed either in acute or right angle flexion depending upon the amount of swelling and circulatory impairment. We commonly make use of a posterior molded plaster splint for this purpose. Post reduction roentgenograms should be made immediately to make sure that complete reduction has been accomplished and that the relations are normal in both planes.

TABLE XIX.—RESULTS OF TREATMENT OF DISLOCATIONS OF THE ELBOW

	Excellent A. F. E.	Good A. F. E.	Fair A. F. E.	Poor A. F. E.	De- tectors
Fresh dislocations treated by closed reduction	13	5			1
Old unreduced disloca- tions treated by open reduction		2 nd	1 st	3 rd	

¹Developed ankylosing tenosynovitis with large mass of tissue lying anterior to head of radius.

²Unreduced dislocation, 6 days old complicated by fracture of capitulum treated by open reduction.

³Unreduced dislocation, 60 days old, complicated by fracture of olecranon treated by open reduction.

⁴Unreduced dislocation, 63 days old, treated by open reduction.

⁵Unreduced dislocation, 36 days old, treated by open reduction.

⁶Unreduced dislocation, 30 days old, successfully reduced by closed manipulation.

⁷Unreduced dislocation, 36 days old, complicated by fracture of coronoid process, treated by open reduction. Developed ankylosing tenosynovitis with ankylosis.

In case of fracture of the medial epicondyle one should make sure that the fragment has not become caught in the joint (see "Fracture of Medial Epicondyle") and that there is no evidence of ulnar palsy.

In uncomplicated dislocations the elbow should be immobilized for a period of from 7 to 10 days at which time massage and mobilization may be started the elbow being supported at right angles by a sling. If there is a complicating fracture it may be necessary to prolong the period of fixation, but it is rarely necessary to make it longer than 2 weeks. Fractures of the radial head or neck with displacement when present as complicating injuries should be subjected to operation with excision of the head of the radius at the end of 6 to 8 days.

The special menace of dislocation is calcifying hematoma which usually develops in front of the anterior capsule of the joint. When this process has started very little can be done to check it, but there can be but little doubt that repeated manipulation of the elbow may be a causative or aggravating factor. Forceful passive movements to increase extension of the elbow are particularly dangerous and should be avoided. Whenever there is slow return of function and the motion is painful and guarded the possibility of the development of this complication should be borne in mind and an X-ray examination made. If beginning cloudiness in the soft parts anterior

to the elbow is demonstrated then the elbow should be put at complete rest. Operative removal of the calcified mass should never be undertaken until after the lapse of 1 year at which time the ossifying process will have reached a stage of quiescence and there will be less chance of recurrence. In 3 of our 30 house patients, ossifying hematoma developed. It caused restriction of motion and limitation of working ability in 2 and resulted in complete ankylosis in the third. Small areas of calcification in the anterior capsule were noted in 4 other patients and may have been responsible for slight limitation of extension of the elbow.

Of the 30 house patients 24 were fresh dislocations and were admitted from a few hours to 3 days after injury. Reduction was accomplished in all by the closed method. One patient had a compound dislocation the lower end of the humerus coming out through a wound on the anterior surface of the arm. Débridement was performed with reduction of the dislocation immediately after admission to the hospital and the wound healed without infection. There were 6 patients with old unreduced dislocations of the elbow varying in time from 19 to 90 days after injury. Open reduction was performed in all but one. This patient a boy of 12 was admitted 30 days after injury. Closed reduction was performed, but later was discovered to be incomplete. The result in this case was less good than in any other and shows the wisdom of resorting immediately to open operation in any elbow dislocation of more than 3 weeks duration.

The end results more than 1 year after injury are shown in Table XIX. When it is

remembered that 24 out of the 30 house cases were complicated by varying types of fracture, it is gratifying to find such a high proportion of good results. They were classed as excellent or good in 20 patients. The immediate results in the 5 patients listed as unknown were good at the time of leaving the hospital. This accounts for 25 cases or 83 per cent of the entire group. Five of the 6 patients with results listed as poor or fair were only admitted 2 months or more after injury. The results demonstrated that when fresh dislocations of the elbow are recognized and reduced immediately after injury the prognosis is excellent, and no functional impairment need be expected.

SUMMARY

An attempt has been made to present a bird's eye view of the various injuries designated under the title 'Fractures and Dislocations of the Elbow.' The different types of injury have been described, the treatment indicated, and attention called to the special dangers that must be avoided in each of the various fractures and dislocations. End result notes made 1 year or more after discharge from the hospital in 176 of the 439 injuries studied have been presented in order to portray as accurately as possible the outcome that may be expected. We feel justified in concluding that fractures and dislocations of the elbow are not formidable when properly understood and correctly treated. They are a challenge to the surgeon's vigilance and skill, but the victory can be won here as it has been in the other domains of surgery by the use of the weapons already at hand when resourcefully used.

APPENDICITIS

SOME OBSERVATIONS BASED ON A REVIEW OF THREE THOUSAND NINE HUNDRED THIRTEEN OPERATIVE CASES¹

J. M. T. FINNEY, JR., M.D., F.A.C.S., BALTIMORE, MARYLAND

THIS paper is based on the review of 3913 cases of appendicitis in which operations were done in one hospital by many different surgeons, during a period of 30 years. The histories of only such patients are considered as showed definite disease of the appendix, gave a fairly definite history of one or more attacks and were not complicated by other operative procedures at the time of the appendectomy. The cases have arbitrarily been divided into six classes, based on history and operative findings: (1) chronic, those in which the patient had had no definite sharp attack, but rather a grumbling discomfort, and those in which there had been not more than one acute flare up; (2) chronic recurrent, those in which the patient had had two or more definite attacks and an interval operation had been done more or less prophylactically; (3) sub-acute in which the operation was performed during or immediately following either a mild attack, or one which was definitely subsiding; (4) acute unruptured, in a large majority of which the appendix showed gangrenous changes; (5) ruptured with abscess, in which there were definite signs of an attempt to wall off the released infection; and (6) ruptured with peritonitis, in which there was a fairly general or spreading infection with little or no evidence of attempt at localization. (In some instances particularly the earlier cases in which the histories were rather inadequate or indefinite it has been rather difficult to be perfectly accurate in this classification, but in general, the cases more or less automatically fall into their proper groups.) It is not so much the purpose of this paper to discuss the literature, which is far too voluminous to be adequately covered in a communication such as this, nor to boast of or excuse mortality statistics—which as a matter of fact conform pretty closely to many others which have been published—as to search for any differences ob-

servable during this 30 year period, any changes in the character of the operative cases, or in the results obtained and to draw such inferences as may seem warranted from the massed material at hand. It would require much more than our allotted time even to touch on all phases and an endless number of percentages and charts could be offered for consideration, but in this particular study we shall endeavor to limit ourselves to those which have some definite interest or purpose to bring out certain points which seem worthy of special attention or discussion. It is our hope that at some later date we may codify these figures in a more extended and detailed article, if such should seem worth while.

In the cases under review the patients were all operated upon in the old Union Protestant Infirmary and its present successor the Union Memorial Hospital of Baltimore, Maryland between the years 1900 and 1930. There are 60 outside surgeons represented, many of them, however by only 1 or 2 cases, and 39 different house surgeons are responsible for the group listed under resident's cases. So that I think we may fairly say that the results are those which may be expected of the average surgeon and not of the superman. There are a total of 3913 cases listed almost equally divided as to sex, 2,019 males and 1,894 females. The oldest was 90 years, the youngest 13 months. Of these a total of 3,201—1,647 males and 1,554 females—were operated upon by the visiting surgeons, and 712—372 males and 340 females—by the house staff. In the entire group there were 91 deaths—67 male and 24 female—a mortality rate of 2.35 per cent total, or (and this is an interesting point which will be dealt with more in detail later) 3.38 per cent for males and 1.26 per cent females; the former almost three times the latter. Of these 91 deaths, 70 are chargeable to the visiting staff—51 males and 19 females—for

¹Presented before the Clinical Congress of the American College of Surgeons, October 27-28, 1934.

(Grand total 1,593 cases—51 deaths—3.23 per cent mortality rate.)

a mortality rate of 2.10 per cent combined, or 3.10 per cent male and 1.22 per cent female, 21 occurred in house cases—16 male and 5 female—with a mortality rate of 2.95 per cent combined, or 4.30 per cent male and 1.47 per cent female. This slight difference might indicate on the surface the advantage of the added years of experience and practise on the side of the visiting surgeon but actually it may be adequately explained by the greater preponderance of the more serious and advanced cases occurring in the house surgeon's group—relatively there were approximately 20 per cent more ruptured appendices on his list than on the visiting surgeon's. In fact his mortality rate in handling the latter cases is almost identically that of the surgeon of widest experience and the greatest number of cases on the visiting staff differing by only .04 per cent. This would certainly seem to indicate that in the hands of a reasonably competent surgeon, there is a certain basic minimum rate, below which we cannot go through surgery alone but which must be bettered, if at all, by reduction in the number of such cases which come to operation.

This being the situation, what improvement has been made during the past 30 years

in getting the acute cases before rupture occurs? In considering this phase we will eliminate the chronic and chronic recurrent groups from the figures. This may not be altogether fair, as assuredly the best way to avoid the rupture of an appendix is to remove it before a really acute attack occurs and frankly, the more we see of the results of ruptured appendices the more we lean toward the prophylactic removal of that appendage on the slightest provocation—and we believe we can justify that stand a little later in the course of this paper by ample figures. But for the present let us consider what advance has been made in the early diagnosis and surgical treatment of the acute attack. In the 5 years from 1900 to 1905, in the four groups—subacute, acute unruptured ruptured with abscess, and ruptured with peritonitis—there were a total of 229 cases, of which 105 or 45.85 per cent, had ruptured. From 1906 to 1910 there were 370 with 156 or 42.16 per cent, 1911 to 1915, 353, with 119, or 33.71 per cent, 1916 to 1920 376 with 86, or 22.87 per cent, 1921 to 1925, 383, with 95 or 24.80 per cent, and 1926 to 1930—in the larger new hospital, 644, with 117 or 18.17 per cent. Thus, to be sure, shows a

definite, gradual practically uninterrupted improvement but is it not still a rather sad commentary that in almost 1 of every 5 cases rupture has occurred when the patients reach the operating room? And this in a hospital where a large majority of the acute cases are patients who come from the city proper or the surrounding suburban area, with an abundant supply of doctors, and good transportation facilities. It does seem that we could reasonably expect considerable improvement in this quarter.

Are there any underlying reasons for this state of affairs which we might remedy? We

feel that there are several. In the first place the administration of cathartics in cases of abdominal pain, to which much attention has been directed by various authors. We do not feel that all cases of ruptured appendices are directly traceable to their use, nor do we feel that their exhibition is invariably followed by disaster but there is abundant reason to believe that they are a potent predisposing factor in many instances, and that the avoidance of their employment cannot be too strongly stressed. In our group of cases, only those were tabulated in whose histories there was a definite statement as to whether or not a cathartic had been administered—nothing was taken for granted—consequently only a relatively small number appears in the table. Also probably fortunately for the

TABLE VII—DURATION OF ATTACK BEFORE OPERATION (SURVIVORS)

Group	Sex	Under 6 hours	6-12 hours	12-18 hours	18-24 hours	24-30 hours	30-36 hours	36-48 hours	48-72 hours	72-96 hours	96-120 hours	Over 120 hours	Duration unknown

individual concerned a fair number of those who were listed as having received a laxative had also a notation of having vomited it fairly promptly. In the subacute group of 199 cases in which a definite statement was made 61 or 30.65 per cent had had a cathartic, in the acute unruptured group of 505 cases 205 or 40.59 per cent in the ruptured with abscess of 180 cases 109 or 60.56 per cent in the ruptured with peritonitis of 91 cases 56 or 61.54 per cent. These all survived operation but among the fatalities though the figures are small the discrepancies are even greater. As there were no deaths in the subacute group only the last 3 need be considered. Of 16 deaths in the acute unruptured group only 5 are listed of whom only 1 or 20.0 per cent had cathartics. Of 21 deaths in the abscess group 6 are listed of whom 5 or 83.33 per cent had cathartics. And of the 52 deaths in the peritonitis group 26—just half—are listed of whom 19 or 73.08 per cent had cathartics. The campaign to educate the layman the druggist and the doctor against the indiscriminate administration of laxatives should be pushed to the utmost. Secondly—and we believe even more important still—the doctor and by all means the medical student should be most forcefully warned of and taught not only the signs and symptoms of the typical case of appendicitis but also the striking absence of such guide posts exhibited in many instances. This latter point we feel is touched on far too lightly when waiting for them to appear means to the patient much the same thing as waiting for the sentinel glands above the left clavicle to clinch the diagnosis of carcinoma of the

stomach. It seems impossible graphically to chart signs and symptoms on an accurate percentage basis in such a way that it would mean anything or be of any great value. Suffice it to say that the cardinal points of constipation generalized pain shifting to the right lower quadrant nausea vomiting point tenderness muscle spasm and rigidity moderate temperature and pulse elevation high leucocyte count with increased polymorphonuclear differential and so forth all these things are present in a few cases a few of them are present in the majority of cases and virtually none of them are present in quite an appreciable number of cases. Of them all the most constant and useful seem to be localized point tenderness and a relative increase in the polymorphonuclear leucocytes—the latter rather than the white blood count taken as a whole. We would take this opportunity to warn against too great dependence upon the white count as an infallible index of the degree of the inflammatory process. Of 1,162 counts recorded in the last 3 groups—acute abscess and peritonitis—93 or 8 per cent were under 10,000 and of these 17 were in cases in which the appendix had already ruptured. On the other hand the average for the counts in the different groups was about as one would expect in 103 chronic cases 9,017, 79 chronic recurrent 9,383, 399 subacute 10,878, 785 acute unruptured 16,361, 233 ruptured with abscess 18,696, and 144 ruptured with peritonitis 17,951. In every group but one—the acute unruptured—the male counts averaged slightly less than the female. The average percentage of polymorphonuclear leucocytes in the 6 groups were 67.7 per cent 67.1 per

TABLE VIII.—DURATION OF ATTACK BEFORE OPERATION (DEATHS)

Group	Sex	Under 6 hours	6-12 hours	12-24 hours	24-48 hours	48-72 hours	72-96 hours	96-120 hours	120-144 hours	Over 144 hours	Duration

cent 73.9 per cent 84.0 per cent, 84.8 per cent and 87.6 per cent, respectively. Thirdly, the all important factor of time. Unfortunately somebody must once have promulgated the theory that an appendix does not rupture in less than 48 hours from the onset of the attack, and much more unfortunately he seems still to have numerous disciples. In point of fact 2 of our series had ruptured in less than 6 hours, 43 at the end of 24 hours and 164 or 24.2 per cent, by the time the 48 hours were up and of these 19 or 11.6 per cent, died. Many of the other cases in the duration unknown group or in those operated upon after a greater time had elapsed would probably fall in this group were all the facts known, but we are dealing only with known facts, and these figures are amply sufficient to prove our contentions, namely that ordinarily the time to operate is as soon as the appendix can be reasonably suspected that the use of an 'ice-cap to scatter' the trouble too often does just that, and that the only safe appendix is one in a bottle.

TABLE IX.—MORTALITY RATES IN GROUPS SEPARATELY AND COMBINED

Group	Cases	Deaths	Mortality rate
Group A—early or prophylactic operation			
Chronic	827	1	0.12
Recurrent	731	0	0.00
Subacute	548	0	0.00
Total Group A	2106	1	0.045
Group B—operation during acute attack			
Acute unruptured	1120	16	1.43
Ruptured with abscess	438	20	4.57
Ruptured with peritonitis	240	53	22.08
Total Group B	1807	89	4.93

B is more than 50 times A

It would seem to us much better to remove a half a dozen relatively normal appendices by emergency operations, than to be responsible for the consequences which may attend waiting too long on one.

We fully realize that the statement just made may sound very radical to some, but again we can show that the figures back us up. In the chronic group out of 827 cases there was 1 death—a mortality rate of 0.12 per cent, in the 731 recurrents, 1 death or 0.14 per cent and in 548 subacutes, not a single death. In other words by prophylactic or early operation we can offer the patient a mortality rate—2106 cases with 2 deaths—of 0.095 per cent. Over against this, if the attack proceeds to the acute gangrenous stage, while the chances are still good—1120 cases with 16 deaths mortality rate 1.43 per cent—the risk has been increased approximately fifteen times—and the appendix still not ruptured. Next in the abscess group—438 cases with 20 deaths, a mortality rate of 4.57 per cent—the danger increases again by more than three times. And finally in the peritonitis group—240 cases with 53 deaths, a mortality rate of 22.08 per cent—we multiply the chance taken by five, a total increase over the early groups of more than 225 times. Is it worth the risk, when the best the patient can look forward to if that particular attack does subside under expectant treatment is the probability of another later one—time, place, and circumstances unknown—plus the ever present chance that the current attack will not subside anyhow? It really seems to us that, paradoxically the radical stand is the more conservative.

But there is one more argument in favor of our contention—what of the time the patient

TABLE A.—AVERAGE DAYS HOSPITALIZATION BY GROUPS IN FIVE YEAR PERIODS

Group	Sex	1900-1905	1906-1910	1911-1915	1916-1920	1921-1925	1926-1930	General average	Average combined sexes

	M		11.7	13.5	13.3	11.5	11.5	12.3	
Subacute	F	17.4	12.3	14.9	12.9	12.5	11.2	13.5	12.9
	M	16.4	12.6	11.4	11.1	11.1	12.1	12.4	
Acute	F	18.7	14.7	13.3	13.6	13.7	12.3	14.7	14.3
	M	17.6	13.0	13.2	13.0	13.6	12.1	13.0	
Abscess	F	30.0	28.2	32.7	29.7	24.5	31.1	29.4	28.8
	M	31.1	30.5	30.9	25.6	26.4	24.9	28.2	
Peritonitis	F	48.6	36.5	39.8	41.8	36.8	25.7	38.1	34.7
	M	35.1	28.1	35.3	28.4	30.0	26.9	31.3	

may reasonably expect to be laid up in the hospital and the consequent economic problem to be faced—not to mention the subsequent period of convalescence which naturally is much longer in the more serious groups of cases, but which cannot be accurately reduced to figures? In the chronic group the average duration of hospitalization was 15.5 days—this figure results from the higher percentage of exploratory right rectus incisions in this group the muscle splitting McBurney incision predominating in the others—in the recurrent, 12.7 days in the subacute 12.9 days, in the acute unruptured 14.3 days in the ruptured with abscess, 28.8 days, and in the ruptured with peritonitis 34.7 days. These figures being averages of course cover the entire hospital stay, in many instances greatly lengthened not only by complications, but also by other subsequent operative or medical procedures in no way related to the appendectomy (Parenthetically by the same token the mortality statistics, as given are not an entirely accurate index, as the deaths include several in no way dependent upon the appendectomy but occurring during the period of

hospitalization and hence indirectly chargeable to it. We hope to remedy these defects at some later date in a paper analyzing the deaths and complications, but at present, time does not permit it.) In all groups the hospitalization for females averaged somewhat longer than for males. Also in all groups the average time for the last 5 year period—1926 to 1930—is appreciably less than the corresponding average for the full 30 year period an indication at least of better surgical and nursing care, as well as fewer and less prolonged complications. But the difference between the unruptured and the ruptured groups remains just as striking.

We will not attempt to summarize these somewhat rambling and at times we fear inco-ordinated remarks, further than to stress once again one fact, which strikes home most forcibly, and which we feel should be given especial emphasis namely, that even in this enlightened and progressive age when public attention is being constantly directed toward various health facts or fancies almost 20 per cent of inflamed appendices have already ruptured when they reach the surgeon

THE HOPEFUL PROGNOSIS IN CASES OF CARCINOMA OF THE COLON¹

FRID W. RANKIN, M.D., F.A.C.S., ROCHESTER, MINNESOTA

Division of Surgery The Mayo Clinic

PAUL F. OLSON, M.D., ROCHESTER, MINNESOTA

Fellow in Surgery The Mayo Foundation

THE assertion is frequently made that carcinoma of the colon is attended by favorable prognosis if the growth is radically extirpated before visceral metastasis has developed. Such has been our observation and experience. A study of 453 cases in which operation was performed at The Mayo Clinic between 1907 and 1927 was undertaken to evaluate the factors entering into the prognosis.

Influences which modify the outlook following surgical treatment of carcinoma of the colon group themselves into extrinsic and intrinsic elements; the former represent general conditions of the host and certain conditions local to the neoplasm, whereas the latter represent the intensity of the malignant cells.

I. Extrinsic influences

1. General

- Age of patient
- Loss of weight
- Anemia
- General debility
- Cardiovascular and renal impairment
- Co-existing chronic debilitating diseases, such as diabetes and tuberculosis
- Duration of growth
- Direction of growth
- Glandular metastasis
- Lymphocytic infiltration
- Fibrosis
- Hyalinization

2. Local

- Site
- Fixation
- Perforation with or without abscess or formation of fistula

II. Intrinsic influences

- Activity of the neoplastic cells, especially their ability to differentiate and approach the normal state

Consideration of these two types of influence, extrinsic and intrinsic, has led us to the firm conviction that the intrinsic malignancy of the carcinomatous cell affects in direct ratio all of the other factors which modify it. We do not feel that clinical scientific observa-

tions and general conditions which influence the prognosis should be excluded from grave consideration, but we feel that it is incontrovertible that the activity of the neoplastic cell is the primary factor which decides between longevity and early recurrence. Unquestionably such factors as involvement of lymph nodes and distant or hepatic metastasis affect the length of life after operation in direct proportion to their presence or absence. We show later in this paper that involvement of nodes is directly dependent on, and that its extent is proportional to, the grade of the malignancy. Such local conditions as fixation of the growth, perforation, penetration and formation of abscess affect the operability of the growth, but they are merely local influencing factors which are usually the result either of intense activity of the carcinomatous cell or of prolonged neglect in the absence of symptoms.

The situation of the carcinoma unquestionably is an important factor. Carcinoma of the right half of the colon, for a reason which we are not able to explain satisfactorily to our selves, is of better prognosis than of carcinoma of the left half. In cases of carcinoma of certain segments of the right part of the colon, for example the cæcum, there is a higher percentage of 5 year cures, or of freedom from recurrence, than when other segments are involved. Such general conditions as anemia, cardio-renal insufficiency, co-existing debilitating diseases, and loss of weight obviously are only modifying factors and influence the prognosis by their effect on the condition of the patient.

Age is a very important factor in prognosis. It is a well known fact, proved frequently by many observers, that a youthful host to a malignant growth is at a decided disadvantage compared to a person past middle age. This we believe is explained by the activity of the

tissue cells themselves. The elasticity of youthful tissue in contradistinction to that of senescence is less hostile to carcinoma and more readily succumbs to its invasion.

The size of the growth as has frequently been shown by many observers and our experience corroborates them has little if anything to do with the outlook. The size and pathological type differ distinctly in the two halves of the large bowel and there is no evidence for the conclusion that in the main large growths entail a poorer prognosis than small growths. As a matter of fact it is not uncommon for a surgeon on extirpating a huge growth which he has considered to be on the borderline of operability to find absence of metastasis to nodes and a low grade of malignancy the tumefaction being largely the result of inflammatory reaction. Such types of growth often give the most satisfactory prognosis particularly if they are situated in the right half of the colon. On the other hand it is not an uncommon experience to explore a small rectal or sigmoidal growth which is perfectly operable locally and at the same time to find multiple hepatic metastasis contra indicating resection of the growth except occasionally as a palliative measure.

The factor of direction of growth unquestionably has some bearing on the outcome. It is shown that growths which protrude into the lumen of the bowel give better prognosis by a considerable percentage in a large series than growths which extend toward the serosa. Because these intraluminal growths progress away from the nodes that are in immediate juxtaposition to the bowel and because they are usually of the papillary or adenoid type and therefore of lower grade of malignancy they influence the prognosis favorably. On the other hand the smaller sessile growths which extend toward the serosa frequently are of higher grade of malignancy and metastasize by way of the lymphatic system at an earlier date.

Concerning intrinsic factors the differentiation or lack of differentiation of the carcinoma cells is we believe the most important single influence on prognosis reacting as it does either directly or indirectly on all of the other modifying conditions. The varied mi-

croscopic appearance of malignant cells occurring in the same situation has long been thought to have prognostic significance and conjectures as to the degree of malignancy were based on such observations as the relative number of mitotic figures the staining reaction of the malignant cells and their invasiveness. Among other factors similarly differentiation was suggested but it remained for Broders to call attention to the real prognostic significance of differentiation to prove his contention by large series of cases both of squamous cell epithelioma and of adenocarcinoma and to provide a system for the grading of malignancy which we believe is the most important single factor in prognosis affecting as it does directly or indirectly all extrinsic factors.

Rankin and Broders in 1918 demonstrated that definite correlation exists between the degree of malignancy as judged by Broders system of grading and the ultimate results to be obtained from surgical excision of carcinoma of the rectum. In making a similar study of lesions in the colon we have followed the rules laid down by him in 1920 in his article on the grading of carcinoma of the lip (modified in 1925) in which he evaluated the degree of malignancy in terms of grades 1 to 4.

PATHOLOGICAL OBSERVATIONS

In order to study to the best advantage the influences on prognosis of the pathological variations all other variable factors are to be eliminated as largely as possible. The time that has elapsed between the appearance of the tumor and the date of its removal is of course a very important variant in the matter of prognosis. An attempt to control this factor is made by a rigid selection of cases only those cases being considered in which the malignant growth was resectable in which there was no demonstrable hepatic metastasis and in which therefore closure was made at the end of the operation with a hopeful prognosis. For the same reason cases in which death occurred immediately after operation are also excluded.

From the statistical standpoint only those cases were considered in which patients were known to have died of recurrence or to have

TABLE I.—SIZE OF CARCINOMATA OF PATIENTS FREE FROM RECURRENCE AFTER FIVE YEARS AS COMPARED WITH PATIENTS WHO SUBSEQUENTLY HAD RECURRENCE

	Cecum	Right	Left	Sigmoid
Dead (cases)	37	44	46	63
Size (average)	7.7 cm.	7.1 cm.	6.3 cm.	5 cm.
Cures (cases)	47	59	54	73
Size (average)	7 cm.	7.2 cm.	5.7 cm.	5.4 cm.

been living more than 5 years free from recurrence. In each case of recurrence the exact number of months of postoperative life was known. Thus, the series ranges from patients who died in the second month after operation to patients who were living 24 years after operation. Selected according to the standards before mentioned there were 453 cases available for study.

The surgical pathological specimens were studied from five aspects: (1) size (2) direction of growth that is whether the tumor was projecting into the lumen or invading the serosa (3) involvement of lymph nodes (4) grade of malignancy as determined by degree of cellular differentiation and (5) a comparison of mucoid carcinomata with the more solid forms.

Carcinomata of the rectum and rectosigmoid were not included in this study. Due to the physiological and anatomical differences between the right and the left halves of the colon the series had been divided in accordance with whether the right or left half of the colon was involved, the point of division was the middle of the transverse colon.

The greatest diameter of the growth was considered as the best index in evaluating the effect of size on the prognosis. In Table I is given the average size of the carcinomata of patients who subsequently had recurrences, as compared with the average size of carcinomata of those who obtained cure for 5 or more years. The group labeled right includes the ascending colon, the hepatic flexure and the right half of the transverse colon. The group labeled left includes the left half of the transverse colon, the splenic flexure, and the descending colon.

From Table I it is seen that in no group did the patients with poor results have appreciably larger carcinomata than did those who

	Total	Dead	5-year cures	Per cent cured
Right half of colon including cecum	187	81	106	57.6
Left half of colon including sigmoid	266	139	127	47.7
Total	453	220	233	51.3

obtained good results. When the four groups are averaged together it is found that the patients who died of recurrence had tumors which averaged less than 0.2 centimeter greater (measured by the longest diameter) than those of patients who lived more than 5 years. The inference is that size has little to do with the prognosis of resectable carcinomata of the colon.

It is interesting to observe that the growths in the right half of the colon were larger than those in the left half and that those of the cecum were of largest average size, whereas those of the sigmoid were smallest. As will be observed in Table II, however, the lesions of the sigmoid and left half of the colon not only do not give a better prognosis, but actually give a somewhat poorer prognosis than do the tumors of the right portion of the colon and cecum.

It has been noted that those malignant growths which project into the lumen give a better result than do those of which the dominant direction of growth is toward the serosa. A lesion which projects itself into the fecal stream will give rise to symptoms of obstruction or of bleeding earlier, whereas a lesion which invades the serosa will more quickly reach the lymphatic structures and will be disseminated sooner. As FitzGibbon and Rankin have demonstrated, colonic carcinomata not infrequently arise on the basis of polyps, and we found that it is the polypoid carcinomata which assume considerable proportions (while projecting into the lumen) without serosal involvement taking place. From the prognostic standpoint it is of interest to observe that of the 24 cases which FitzGibbon and Rankin reported of carcinomata which demonstrably had their origin in polyps 22 were of the lower grades of malignancy.

TABLE III — DOMINANT DIRECTION OF GROWTH

	Toward lumen		Toward serosa	
Average postoperative life of patients with recurrence, months	32	5	21	9
Percentage of 5 year cures	63		41	

TABLE IV — NODAL INVOLVEMENT

	Right half of colon including caecum (18 cases)		Left half of colon, including sigmoid (106 cases)	
	With nodal involvement		Without nodal involvement	
Incidence	34 per cent		31 per cent	
Average postoperative life of patients with recurrence, months	15	7	25	6
Percentage of 5 year cures	39		66	

In Table III may be seen the results of our study on the direction of growth and it is apparent that carcinomata projecting into the lumen of the colon give a considerably higher proportion of successful results than do those with invasion of the serosa.

When dissemination of a malignant growth through the lymphatic channels begins the first sign of the invasion is usually to be found in the local lymph nodes. When only these first outposts are involved complete surgical removal is still possible but their involvement makes the surgeon fearful that the malignancy has already become disseminated further and that undemonstrable distant metastasis has occurred. In Table IV are presented the results of our prognostic studies in relation to involvement of lymph nodes in colonic lesions.

In a recent study on the prognosis of carcinomata of the rectum Dukes divided the gross specimens into three groups: those with involvement of lymph nodes; those without involvement of lymph nodes but with extension into the serosa; and those without either involvement of lymph nodes or invasion of serosa. He found the prognosis to be best in those cases in which there was not extension and nodes were not involved; next best in the cases in which there was only serosal extension and worst in those in which the nodes were involved. In our cases of carcinoma of the colon the relationship of extension to prognosis was the same but we found nodal in-

TABLE V — GRADING OF MALIGNANCY IN RELATION TO POSTOPERATIVE LENGTH OF LIFE

	Grade			
	1	2	3	4
Right half of colon (187 cases)				
Incidence per cent	16	53	21	10
Average postoperative life of patients with recurrence, months	25	8	22	8
Percentage of 5 year cures	68	60	48	3
Left half of colon (106 cases)				
Incidence per cent	13	67	16	4
Average postoperative life of patients with recurrence, months	13	7	26	5
Percentage of 5 year cures	63	51	30	18

TABLE VI — GRADE OF MALIGNANCY IN RELATION TO INVOLVEMENT OF LYMPH NODES

	Grade			
	1	2	3	4
With nodal involvement (147 specimens)				
Incidence per cent	11	55	23	11
Average postoperative life of patients with recurrence, months	24	6	19	14
Percentage of 5 year cures	47	41	15	25
Without nodal involvement (106 specimens)				
Incidence per cent	16	63	16	5
Average postoperative life of patients with recurrence, months	34	4	27	7
Percentage of 5 year cures	72	60	54	36

volvement to be much the most significant factor.

It is apparent from Table V how close the correlation is between the grade of malignancy and the prognosis not only as concerns ultimate cure but also in the rapidity with which recurrences are fatal.

Pathologically carcinomata of the colon and of the rectum have much in common. It is interesting to observe that more than half of the malignant growths of the colon were of grade 2 and that a similar incidence was demonstrated relative to the rectum by Rankin and Broders.

Having concluded the study of the various individual factors in prognosis it is tempting to correlate each factor with the others, individually and collectively. The possibilities are, however, too numerous and the results would be more confusing than clarifying. One such correlation was nevertheless indulged in, namely the relationship between grading and involvement of lymph nodes.

TABLE VII—POSTOPERATIVE LIFE IN 44 CASES OF MUCOID CARCINOMA COMPARED WITH 409 CASES OF NON MUCOID CARCINOMA

	Mucoid	Non-mucoid
Incidence, per cent	10	
Average postoperative life of patients with recurrence, months	17.6	22.8
Percentage of 5 year cures	43	52

It is noted in Table VI that grades 1 and 2 were relatively more frequent among the specimens obtained from patients who had no nodal involvement whereas grades 3 and 4 on the contrary were relatively more common among the specimens from patients with involved nodes. In view of this observation it is enlightening to compare the percentages of nodal involvement within the individual grades. In grade 1 28 per cent of the specimens were from patients with involved nodes in grade 2 30 per cent in grade 3 36 per cent and in grade 4 53 per cent. This progressive increase in the incidence of involvement of lymph nodes as one passes to the higher grades of malignancy discloses a definite correlation between the microscopic grade of malignancy and involvement of the regional nodes.

Further study of Table VI however disclosed that the grade exerts as much influence on prognosis in the group in which nodes were not involved as it does in the group in which they were involved and that nodal involvement operates prognostically quite as well in any one grade as it does in any other.

In perusing the literature one will observe that there is considerable difference of opinion as to the malignancy of mucoid carcinomata. Many regard the excess of mucinous substance as a degenerative phenomenon. Parham referred to it as an 'uncontrolled function of secretion' and expressed the belief that 'mucous formation is a sign of functional differentiation of the carcinoma cells. Opposed to that view however is the observation of Rankin and Chumley that the mucoid carcinomata which are most undifferentiated structurally secrete the most mucinous material. In view of the variation in opinions, it becomes a matter of interest to study the mucoid carcinomata from the prognostic standpoint.

In the series of 453 cases of carcinoma there are 44 of the mucoid type these are compared

with the 409 cases in which there was no excessive mucinous secretion (Table VII). It is evident that in our series the prognostic difference between mucoid and other carcinomata is not great but that the mucoid carcinomata are inclined to give a somewhat poorer prognosis.

In concluding the statistical part of this paper we call attention to the fact that although the factors noted in the tables operate definitely to influence the prognosis in the average of a series no such uniformity is seen when one individual case is compared with others. What is prognostic for the group is the dominant tendency in the individual case.

PRINCIPLES OF OPERATION AND OPERABILITY

Considering the advanced stage of the disease at which so many perhaps the majority of patients with lesions in the colon present themselves for examination and treatment one must consider as fundamentals of surgical extirpation attention to obstruction, and rehabilitation. Decompression of the colon then becomes the primary object of all treatment preliminary to resection. It is incontrovertible that obstruction in one of its forms is present in more than three-fourths of the cases of growths of the left and middle portions of the colon. The debilitation, anemia, and cachexia following growths in the right half of the colon are secondary physiological disturbances. It is not necessary that obstruction is present in such a form as to cause hypertrophy and dilatation of the bowel proximal to the growth, but simply dilatation to a small degree should be looked on as being evidence of a certain amount of obstruction. It is well known that obstruction and ulceration enormously increase the permeability of the colonic wall. Given a foul ulcerating growth bathed in a bacteria-laden fecal current there is always present a large amount of infection. When factors favorable to increasing permeability are present the pericolic tissues immediately adjacent to the growth are especially tender and the spread of organisms by the examining hand most frequently accounts for ensuing peritonitis.

Local conditions in the bowel, secondary to obstruction, become unfavorable for primary

resection and anastomosis particularly if they are in the left half of the colon. The wall of the bowel is thickened and edematous and the blood supply is encroached on. The blood supply of the colon however is much more constant than usually has been believed. Steward's work in this connection is most enlightening and instructive. Failure of resections of the last half of the colon in the face of slight obstruction perhaps is due in the majority of instances more to infection in the wall of the colon than to failure of the blood supply *per se* although unquestionably both conditions must be given consideration. In most cases of carcinoma of the colon which occur in middle age or late years of life obstruction is followed by a sequence of events which rapidly produces dehydration and undermines vital processes. When one remembers that the patients do not appear for examination until 10 to 12 months have elapsed the fact is appreciated that the malignant offensive has had ample opportunity to effect attainment of nature's mechanism.

Decompression of the colon is accomplished either by medical measures which are favorably instituted against chronic obstruction or even against subacute obstruction but which obviously must be supplemented by surgical drainage in the cases of increasing or acute obstruction. We have found it possible by medical measures to relieve practically all chronic obstruction to such a degree that the patients were in favorable condition for operation but local conditions modify this factor and occasionally it may not be possible to effect decompression in subacute obstruction except surgically. Surgical decompression in the presence of acute obstruction due to carcinoma is best accomplished by blind caecostomy. Following the suggestions in the paper of Burgess published some years ago we have been much impressed by the favorable employment of caecostomy without exploration when the malignancy produces an acute obstruction without premonitory symptoms. If a caecostomy is done by the Hendon method with a bell catheter "Witzelizing" the bowel in its introduction the surgeon may subsequently, after the patient has recovered, investigate the bowel, localize the growth, and

at the second stage explore the abdomen and institute whatever measures of extirpation seem indicated.

Rehabilitation is a second important fundamental in dealing with carcinomata of the colon. Emergency operations are rarely demanded in such cases. The few in which emergency operation is essential need only decompression because of acute obstruction. Consequently these lesions may be considered chronic ailments which permit of more leisurely examination and selection of the optimal time for operation. By overcoming the dehydration and desiccation by blood transfusion and adequate intake of fluid as well as by a nourishing dietary regimen, one feels that operation is undertaken with less risk.

A third feature of the program of rehabilitation after operation has been the institution, as a routine of intraperitoneal vaccination in an attempt to elevate resistance and overcome infection. We have now used this in more than 600 cases and feel that it is a distinctly advantageous procedure. Although it unquestionably is of small value when utilized alone, and when other fundamental principles of selection for operation are disregarded yet in a sequence of events preliminary to operation we believe it has a distinctly important position.

A fourth feature of the attack on carcinoma of the colon has been in our experience, an advantageous one namely institution of graded procedures for their removal. Obviously, it is not necessary in all cases to employ an operation in two or three stages to remove these growths. Certainly, the more sturdy patients with small growths which have been discovered early occasionally may be submitted to resection in one stage with favorable mortality. This is the exception rather than the rule however and we are firmly convinced that a wider range of operability, as well as a more radical type of operation, may be accomplished by undertaking removal in multiple stages.

The right and left halves of the colon, differing as they do physiologically and anatomically are different problems technically when it comes to a question of resection. We believe that the right half of the colon is best removed by an operation in two stages, which consists

of preliminary union of the terminal portion of the ileum and the middle of the transverse colon and at a second stage removal of the entire right half of the colon, 2 to 4 weeks later. The advantage of end-to-side anastomosis is obvious. The object of resection in two stages is to sidetrack an infected growth and drain the right half of the colon while in addition adequate measures of rehabilitation are being substituted. This is not accomplished by lateral union of the ileum and transverse portion of the colon in nearly so satisfactory a manner. A large portion of the fecal current continues to pass over the surface of the carcinoma, and the very object of the maneuver in two stages is largely vitiated.

For growths in the left half of the colon, we have come to employ with satisfaction an obstructive type of resection, which is radical removal of the local growth and the node bearing region in immediate juxtaposition to it leaving a clamp on both ends of the bowel for a period of 48 to 60 hours, and then opening the proximal blade to establish a colonic stoma. The subsequent steps of this operation consist of removal of the diaphragm between the two gun barrels and closure later if necessary. One of us (8) described this operation in a former publication. At The Mayo Clinic it has been employed continuously since with increasing satisfaction in a large group of cases. The mortality rate reported at the time of the original paper has not been maintained at that time one of us (8) reported 31 cases with 1 death. By extending the scope of the operation and perhaps being a little more enthusiastic than was warranted, the mortality rate has risen to 8.6 per cent but the conviction is not without its merits that a mortality rate of less than 10 per cent in resections of the left half of the colon is perhaps justifiable if the figures of operability run about 50 per cent. This form of resection is obviously strongly contra indicated in the face of obstruction and when we have not been able to decompress the colon satisfactorily prior to exploration we have abandoned the method in favor of an operation for drainage such as cecostomy or colostomy followed at a second stage by some type of resection. The resection still may be obstructive resection if

the surgeon wishes the objection being that there is the necessity for closing two colonic stomas occasionally but this is not a serious objection. Also secondary resection may be performed, with anastomosis at the same time.

The old type of Mikulicz operation popularized years ago and erroneously named because it was done first by Block many years before we mention only to deprecate except in a very small and closely selected group of cases. It has the disadvantage of implanting carcinomatous cells in the surface of the wound in about 12 per cent of the cases and the percentage of cures that follows its application naturally is lower than in more radical types of maneuver. Given a weak, elderly patient who harbors a carcinoma in a mobile segment of the colon, whose abdominal wall can be rapidly infiltrated by local anesthesia, and the growth pulled out onto the abdominal wall without exploration manipulation, or sacrifice of the blood supply the old type of Mikulicz operation unquestionably is indicated. Further than in this type of case, it has small utility.

OPERABILITY

Operability is so variable in the hands of different surgeons that it is impossible to do more than lay down certain fundamentals, which are subject to modification. Our standards of operability maintain that if there are no demonstrable growths in the liver or if the growth is not firmly fixed to the parietal peritoneum or adjacent viscera, attempts should be made to remove it unless the general condition of the patient is such that operation offers no chance of success. One might even argue that occasionally growths that are mobile and resectable, and yet have metastasized to the liver should be extirpated. With this view we have no quarrel, and occasionally carry out resection of the growth as a palliative measure. The reason for this is that death from carcinoma of the liver is relatively painless making justifiable the risk of eliminating an obstructing ulcerating carcinoma which may attach itself to adjacent viscera. Involvement of lymph nodes provided the nodes are in immediate juxtaposition to the growth, should not hinder resection. It long has been

recognized that it is impossible to tell by palpation alone, whether a node is involved and microscopic section is necessary for this decision. Also, study of this series of cases proves that many patients with growths which were shown at resection to have invaded the nodes have lived long and useful lives without recurrence. Local fixation not infrequently does rule out resection. This is a problem a surgeon must decide on the individual merits of each case. Not infrequently one may remove a uterus to which a sigmoidal carcinoma is attached, or the top of the bladder or a segment of small bowel or a segment of the stomach, without operative mortality and occasionally with a brilliant result. In the main however, such operations are palliative, are undertaken with huge operative risk and extreme care should be exercised before they are undertaken to weigh the advantages and disadvantages to the patient of such a formidable procedure.

Percentages of operability, then, are not very satisfactory gauges from which to draw conclusions. So many factors are concerned that their evaluation is difficult. The highest operability on the colonic and rectal service at the clinic, which we have obtained in recent years, is 68 per cent. Rarely has it ranged below 50 per cent and somewhere between those figures is probably a satisfactory estimate of operability. If it can be maintained with the present low operative mortality rate, if we can resect as a routine over a span of years one of two carcinomata of the colon and rectum as they appear, with a mortality rate ranging from 5 to 10 per cent, we probably will have struck a higher standard than is the average in the surgical world.

OPERATIVE MORTALITY

Hospital mortality unquestionably has been satisfactorily decreased in dealing with malignant lesions of the colon and rectum within the last decade. Although a high rate of mortality still is recognized as inevitable in dealing with these lesions certainly, by co-operative care of surgeon and internist by adequate preliminary decompression and rehabilitation by introduction of intraperitoneal vaccination and selection of more suitable types of opera-

tion for each case the immediate hospital mortality has been reduced. Unquestionably the ratio between hospital mortality and operability is an important index in the consideration of end results following radical surgery. Although every effort should be made to extend the horizon of operability to the utmost compatible with reasonable hospital mortality, it inevitably follows that such cannot be accomplished without a death rate ranging from 5 to 10 per cent.

It long has been recognized that not only is carcinoma of the right half of the colon more favorable for ultimate cure following resection, but also that operation can be performed with lower hospital mortality than if the growth is in the left half. It is not our purpose to consider the factors which enter into this, but our experience in this respect parallels that of other surgeons.

In the study of this particular series of 453 patients with carcinoma of the colon, we included only those who recovered following resection, and who were dismissed from the hospital. In order to obtain some idea of hospital mortality, we reviewed the operations done on the right and left portions of the colon at The Mayo Clinic by the whole group of surgeons during 1930 and 1931. In the right portion of the colon, where the choice of operation was ileocolostomy in one or two stages and resection, there were 84 operations with 9 deaths in hospital or a mortality rate of 10.7 per cent. In the left half on the service of one of us (Rankin), from January 1, 1929 to February 1, 1930, one type of operation that was accepted as a standard but which could not, of course be done in all cases, was obstructive resection, 31 operations were done with 3 deaths in hospital or a mortality rate of 9.6 per cent. Although this is not consonant with the customary mortality, lower with reference to the left than to the right portion of the colon, an average mortality rate of 10 per cent for the whole colon we believe is not unreasonable, provided the operability is not reduced below 50 per cent.

DIVERTICULOSIS AND DIVERTICULITIS WITH PARTICULAR REFERENCE TO THE DEVELOPMENT OF DIVERTICULA OF THE COLON¹

VERNON C. DAVID, M.D. CHICAGO

THE appearance of diverticula in the body is widespread. The most commonly observed sites are the upper and middle portions of the esophagus, the duodenum, the jejunum (Meckel's diverticulum), the colon, and the bladder. The more unusual sites are the larynx, the lower end of the esophagus, the stomach, the ileum, the ureter, the urebra, and the biliary and pancreatic ducts.

The most satisfactory classification of diverticula is probably that based on their origin, into the congenital and acquired types, because so called true diverticula contain all the layers of the structure from which they take origin, may be either congenital or acquired and may eventually change into so called false diverticula. In the latter instance the herniating mucosa and submucosa is the most conspicuous structure present in the false diverticulum.

The large bowel is probably more frequently the seat of diverticula than is any other structure in the body. While large single congenital diverticular sacs in the colon have been described, by far the most common type is the acquired. These may be present in large numbers and may involve all portions of the colon, rarely the rectum, but most frequently the sigmoid colon. As will be shown later, these diverticula may be microscopic in size and consist only of herniation of the mucous membrane through the circular muscle of the bowel or, as we commonly recognize them, they may be the size of a pea or hickory nut and often contain fecaliths. These sacculations of the colon were adequately described by Cruveilhier in 1849, by Virchow in 1853, and Rokitsky in 1856. According to Sommering they were also described in Matthew Ballies' *Morbid Anatomy* in 1794.

The incidence of the involvement of the colon in diverticulosis can perhaps be best emphasized by quoting the report of W. J.

Mayo, in 1930. In this report 2,139 cases were considered. Five to 7 per cent of all colon examinations revealed diverticula. Spriggs and Maxer report that diverticula of the colon were shown in 8.3 per cent of all the patients subjected to gastro-intestinal X-ray examinations. In the Mayo group it was estimated that 5 per cent of adults over 40 years of age have diverticulosis of the colon, whereas, such a diagnosis was made in only 28 patients under 40 years of age. Hartwell and Cecil have reported 2 patients, 7 and 10 years of age, respectively, and Ashhurst 1 patient, 7 years of age, with diverticula of the colon.

The two outstanding etiological factors seem to be age and constipation. Adiposity has been mentioned as a predisposing factor, but diverticulosis of the colon has been observed in many thin patients.

The factors underlying the development of diverticula of the colon have received much thought. There are several anatomical arrangements in the colon that may predispose to diverticulosis. Poirer and Charpey have pointed out that the three longitudinal muscle bands or *taenia* of the colon include practically all of the longitudinal muscle of the colon. Between these *taenia* isolated bits of longitudinal muscle may be found, but in the main the muscularis in these areas is composed of circular muscle alone. The pleated or gathered appearance of the colon is due to the formation of three rows of sacculations between the longitudinal muscle bands (Fig. 1). These sacculations are separated by falseform ridges (Fig. 2) composed of all layers of the intestine, as much mucosal as muscular. The circular muscle is reinforced in them and augmented in volume. These sacculations and ridges of the colon retard the passage of feces and in constipated subjects Charpey observed sacculations of large size, like diverticula, which really were but exaggerations of the normal structures.

¹Presented before the Clinical Congress of the American College of Surgeons, St. Louis, October 17-21, 1932.

In addition anatomically, the penetration of the muscularis by the blood vessels seems to offer areas of weakness in the bowel wall. Klebs first called attention to the possibility of diverticula developing through the areas of penetration of the muscularis by the vessels, and emphasized traction on the mesentery by a faeces loaded bowel as a factor in increasing the size of the vessel openings. Ernst Graser studied this phase of the subject very carefully making serial sections of the bowel wall along the mesenteric attachment. He found several microscopic diverticula which were herniations of the mucosa through the circular muscle. He emphasized as an important factor in the development of diverticula passive hyperemia which dilated the veins and so increased the space of their penetration through the muscularis of the bowel. He wisely observed however that diverticula are not always associated with passive hyperemia. In adverse comment on the theory of Graser Sudsuki studied the sigmoid in 28 heart cases all suffering with passive hyperemia and found diverticula in only 6. He examined 12 other cases of diverticulosis where no passive hyperemia existed.

Von Hansemann observed at autopsy an old man of 85 years who had over 400 diverticula of the ileum jejunum and sigmoid. In the ileum the diverticula were at the mesenteric attachment and at the site of the penetrating vessels. In the sigmoid they were at the antimesenteric border at either side of the tunica where there was little or no relation to penetration of blood vessels.

Considering these points experimentally Herchl Hannon and Goode injected water under pressure into the intestines of corpses and found that rupture of the bowel took place at the mesenteric border. In live dogs, however the same experiment resulted in rupture at the antimesenteric border (Clumpsky Beer). It will also be remembered that when a compressed air hose has been applied to the anus in spirit of playfulness and the colon has been suddenly forcefully dilated rupture of the colon has usually occurred opposite the mesenteric attachment.

Edwin Beer in a most excellent critical review points out that, while the venous

channels through the muscularis may be factors in the development of diverticula at the mesenteric border in diverticula of the colon their most frequent site of development is on either side of the tunica opposite the mesenteric border and into the appendices epiploicae. He believes that muscular deficiency is an important factor. This may be due to wear and tear of age, constipation or muscle degeneration and that through weakened areas by reason of pressure from within caused by constipation, diverticula develop.

Wolf has recently advanced a new theory that due to a disturbance of the neuromuscular system of the intestine there is a dysfunction of the rhythmical contractions of the segments of the large intestine. Eventually a small piece of mucosa is caught up between muscle bundles and forms the beginning of a hernial protrusion.

We have recently studied histologically a number of sigmoid colons containing small diverticula without inflammation as well as the colons of aged subjects in whom no clinical suspicion of diverticulosis existed. It is an interesting fact that if one carefully observes the sigmoid colon of old people at autopsy the normal sacculations (*bossulae* of Poirier and Charpey) are markedly developed and from these can often be expressed small round balls of fecal material. The sections of such bowel taken between the tunica opposite the mesenteric border frequently show microscopic diverticula which do not follow the vessels through the muscularis and consist of herniations of the mucosa and submucosal muscularis and fibrous tissue through the circular muscle (Figs. 3-4). These diverticula show no evidence of inflammatory reaction about them and from the outside of the bowel their presence could not be suspected except in a few instances where small fecaliths may be seen as dark spots in the subserosal fat. These diverticula are really microscopic in size and as far as can be ascertained cause no symptoms and histologically have no evidence of inflammation about them. We believe that they are of frequent occurrence in the old and are a rather common accompaniment of muscular changes, such as the fatty degeneration which occurs in the bowel wall of old

Fig. 1. Drawing showing the sacculated appearance of the large intestine due to ridges composed of circular muscle and mucosa shown in Figure 2 (From Poirer and Charpey)

people. That these diverticula finally protrude through the entire thickness of the bowel wall and usually into the appendices epiploicae is well known. Even at this stage where the neck of the sac penetrating the bowel wall is small and the pouch outside the muscular portion of the bowel wall is the size of a pea and contains a faecalith, evidence of inflammation may be entirely lacking (Fig. 5). Histologically it is seen that the convexity of the diverticulum is covered with mucosa, muscularis mucosa, and the fibrous tissue under the mucosa, but that circular muscle is entirely lacking and that only occasionally a few fibers of the longitudinal muscle is present. It is very easy to see that when inflammation takes place within this sac, it may be the cause of inflammatory processes outside of the bowel wall, such as adhesions, abscess formation, fistula in the neighboring structures, etc. In the histological sections there are areas showing the vessels penetrating the circular muscle of the bowel and creating a real break

Fig. 2. Falseform ridges between the longitudinal muscle lines formed by circular muscle and mucosa which cause the plicated or gathered appearance of the colon (From Poirer and Charpey)

in the muscularis without any tendency for the mucosa to herniate through the muscle (Fig. 6). Conversely along the neck of the diverticulum penetrating the circular muscle there is no particular evidence of large blood vessels (Fig. 7).

It appears then that, in the aged conditions exist in the muscularis which allow an easy herniation of the mucosa and submucosa. This hernia goes between circular bundles and is at first surrounded by them. After completely penetrating the muscularis, the periphery of the sac is covered by mucosa and submucosa consisting of the muscularis mucosa, and fibrous tissue and over this the subserous fat. As the diverticulum increases in size it commonly insinuates itself into the base of an appendix epiploica where the body of the sac enlarges into a globular structure and commonly contains dry faecal material or a real faecal concretion. The neck of the sac is small as it penetrates the muscularis and the opening into the bowel may be very difficult to see. During this whole stage of development no evidence of inflammation may be present in histological study, though it is logical to assume that ideal situations exist for inflammation in the body of the sac, which has a narrow opening into the bowel and may be easily occluded.

Fig. 3. Microscopic acquired diverticulum of the colon opposite the mesenteric attachment between the longitudinal muscle fibres penetrating the circular muscle. Hurling mucosa covered with muscularis mucosa and some circular muscle fibers. There is shown no evidence of inflammation.

Fig. 4. Small acquired diverticulum of colon completely penetrating bowel wall into appendix epiploica. Circular muscle of bowel shown extending part way up sides of the sac and well developed muscularis mucosa completely covering sac. a, Appendix epiploica b circular muscle c muscularis mucosa.

The pathology, symptoms and treatment of diverticulitis will be considered under one head because the symptoms and their treatment depend on the particular pathological process present in any given case.

The literature contains many splendid contributions which will be here but briefly gen-

eralized (Edwin Beer Hartwell and Cecil Watson Mummery Spriggs Telling and Gruner Telling, Judd and Pollock, Case Rankin and Brown and W. J. Mayo) Mayo's classification will be followed as it seems to be not only simple but the most inclusive.

1. *Self-limited diverticulitis* is the most common type (Figs. 8-9). The inflammatory process is limited to the wall of the sac and is characterized by recurrent attacks of abdominal soreness, cramps, irregular bowel habits and gas formation. Because of the feeling of incomplete or unsatisfactory bowel movements, the patient takes cathartics or falls into the hands of a "colonic flusher," both of which habits are bad. The treatment consists in the exclusion of seeds, bran, nuts, coarse undigestible material, and the inclusion of cooked fruit, finely divided cellulose vegetable in the diet. Local application of heat and the tincture of belladonna will relax bowel spasm and control the pain in most instances. The patient should lead a "paraffin life" (DeQuervain) taking mineral oil daily. While cure of this condition is not possible by following the above regimen the

Fig. 5. a Well defined acquired diverticulum of colon herniating through circular muscularis and containing fecal material. b Evidence of inflammation. c Penetration of vessels through circular muscle without any tendency to diverticulosis formation. c Beginning microscopic diverticulosis.

Fig 6 Neck of diverticular sac penetrating circular muscle of colon but with no evidence of large blood vessels accompanying the sac. At a blood vessels penetrating the circular muscle layer without tendency for herniation of the mucosa.

patient usually gets along with reasonable comfort. It should be emphasized that cathartics and large enemas are the worst possible agents to employ.

2 *Peridiverticulitis* A The process may be acute with sudden onset, leading to perforation with peritonitis. Here the symptoms and treatment are the same as in acute perforative peritonitis except that the process is on the left side.

B The process may be chronic with recurrent attacks of local peritonitis with adhesions which occasionally involve the bowel in kinks or volvulus. The symptoms in this group are of local peritonitis or of chronic or acute ileus. In the former the treatment is expectant and palliative and in the latter operative if the process is acute or interferes to a serious degree with intestinal function.

3 *Diverticulitis and peridiverticulitis with abscess formation* may result in entero-intestinal, enterovesical, (Fig 10) enterocolic, or other fistulae. Local abscess formation or retroperitoneal abscess formation beneath the sigmoid or caecum (Fig 11) may give symptoms similar to perinephritic or appendiceal abscess. In this unusual type of extraperitoneal abscess formation the relation to diverticulitis must be kept in mind in order to make a diagnosis. If the process is subacute and a large mass develops, there may be evidence of ileus and a colostomy above the process will be indicated. In enterovesical

fistula this is often desirable and after the acute inflammatory process has receded, the fistulous communication can be disconnected by operation (David). When the process is acute the resemblance to appendiceal abscess or perinephritic abscess makes a differential diagnosis difficult or impossible. Retroperitoneal drainage should be carried out.

Fig 8. Large acquired diverticula of sigmoid colon.

Fig. 9. Multiple diverticula of colon especially involving sigmoid.

Fig. 11. Large diverticula of ascending colon which had suddenly penetrated the bowel and resulted in a retrocecal abscess which simulated acute appendicitis under which diagnosis the patient was operated upon.

Fig. 10. Multiple diverticula of colon with filling defect at a due to chronic inflammatory narrowing and accompanied by an enterovesical fistula at that point. A subhepatic abscess developed later from diverticulitis of the hepatic flexure of the colon.

Fig. 12. Filling defect of sigmoid colon due to inflammation and fibrosis of the bowel by reason of multiple diverticulitis.

4 *Diverticulitis associated with obstruction of the bowel*, giving the symptoms of tumor filling defect in X ray (Fig 12), and in 5 to 10 per cent of the cases blood in the stool (Spriggs) makes a differential diagnosis from carcinoma of the bowel very necessary. The pathological process is one of chronic inflammation of the bowel wall around the diverticula, resulting in fibrosis of the bowel wall and narrowing of the lumen of the bowel. The differential diagnosis from carcinoma is not easy and may be impossible to make. The chronicity of the lesion, the presence of other diverticula, and the absence of blood and pus in the stool favor diverticulitis. The correct diagnosis can be made only at operation in some cases and Daniel Jones properly emphasizes the necessity for operative exploration when bleeding from the bowel is from high up and there is a filling defect in the colon. In differentiating diverticulitis with bleeding from carcinoma of the colon Jones points out that the surgeon will be in error more often if he fails to explore such patients. If the fibrosis of the bowel from diverticulitis reaches the point of obstruction and symptoms of obstruction are present the bowel should be resected, usually after a preliminary caecostomy.

5 *Diverticulitis with carcinoma*. If there is a causal connection between diverticulitis and carcinoma it has not been clearly demonstrated. That diverticulosis and diverticulitis are often noted in the presence of carcinoma is well known and diverticula in close relation

to carcinoma is also observed. It is safe to say that the relation of chronic inflammation to carcinoma is much the same in the bowel as it is elsewhere in the body. The important principle is that early exploration is warranted if any suspicion of carcinoma exists.

HISTORY AND DEVELOPMENT OF THE SURGICAL TREATMENT OF FACIAL PALSY¹

ARTHUR B. DUEL, M.D. F.A.C.S., New York

THERE is a trite saying that "the face is the mirror of the soul."

The crude drawings by the earliest artists as well as the finest portraits by the great masters of painting have depicted character or the state of mind of their subjects, not alone by their positional attitude, but in addition by the expression of the face. Ever since there have been written records, descriptions of facial expression have been employed to portray characters or moods. The historian, the poet, the dramatist, the writer of fiction, the story teller have all leaned quite as heavily on descriptions of facial expressions to depict the vagaries of mind of their characters as they have on the recital of what these persons have said or done.

The constant emotional response in the facial muscles to the vagaries of mind of an individual gradually molds his visage into an almost unmistakable type, certainly evident in a practiced physiognomist and usually as well, to his sophisticated fellow beings.

Volitional changes of expression also are very manifest yet it is the constant play of emotional expressions rather than the voluntary movements which bring about the facial configuration that characterizes the individual.

My present discourse deals exclusively with the lesion known as facial palsy. I need hardly dwell upon the intense misery experienced by the victim. Inasmuch as he or she is deprived completely of what we may call "the language of facial expression," the whole social life of the sufferer is threatened and in many instances the capacity for self maintenance is seriously impaired if not entirely lost.

In my examination of the multitudinous case reports, I have noted that the French observers depend largely upon the word *grotesque* to describe the facial appearance of the patient.

Considering the pitiful nature of the results of the lesion it is not surprising to find, in the

medical literature dealing with the subject evidence both of the deepest sympathy on the part of the surgeon or physician and an eager grasping at any remedy that promises complete or even partial recovery.

In a chronological bibliography beginning in the year 1776 which was prepared for me at the New York Academy of Medicine, I found myself confronted by some 1829 articles, all dealing with facial palsy. Some of these articles are merely case reports others deal with the probable cause of the lesion others with the then accepted remedies.

Up to the year 1879 there is no recorded attempt to "cure" facial palsy by surgical methods. Drobnik at that time anastomosed the spinal accessory to the facial (10).

Occasionally there is keen vision into the possibilities of surgery based on recoveries which followed spontaneous or surgical cures of suppurative conditions in the middle ear or mastoid bone.

The writings of that great observer Sir Charles Bell well over a century ago will always be a delight and inspiration to all who may be interested in this particular field (3). His classical work published in 1822 on *The Anatomy and Philosophy of Expression* embodies an analysis of emotional and voluntary expression in man and animals based on a very exhaustive anatomical and physiological research. He pointed out the elaborate system of muscles provided for the infinite shades of emotional expression in humans as compared with the simpler outfit provided in the lower animals to meet their requirements.

About the year 1890 keen observers in the treatment of facial palsy had discerned that when the lesion had resulted from suppurating ears or mastoiditis recovery from the paralysis often followed the arrest of the purulent discharge whether this occurred spontaneously or by operative interference.

When surgery of the temporal bone had so advanced that operators no longer feared to

Fig. 1. At time of operation, March 18, 1931

Fig. 2. In repose 14 months later

Fig. 3. Showing emotional response 14 months later

invade this particular region the results were two-fold on the one hand there were those who were possessed of an extreme fear lest they should even touch the facial nerve. Facial paralysis must be avoided at all costs! On the other hand there were those who fired by overenthusiasm or overconfidence, were less cautious. Consequently unskilled surgery of the temporal bone brought with it an ever increasing number of cases of accidental facial paralysis.

Confronted by these lamentable facts in the next decade constructive efforts to repair the palsies resulting from these accidents were made by several men.

As early as 1895, Sir Charles Ballance (1) united the distal end of a divided facial nerve to the side of the spinal accessory nerve. The face responded a few months later to faradic stimulation and there appeared a partial voluntary control of the facial muscles together with marked associated movements of the shoulder. In 1898, Faure (12) united the facial to a branch of the spinal accessory. Then followed in rapid succession experiments by Barrago-Ciarella (5) and Manasse (18). Their efforts were confined to anastomosis of the facial nerve with adjacent nerves in the neck.

Without attempting to give a complete survey of this work, I may mention Ballance

Watson Williams (22) and Colledge in England. Gluck (14), Kummer (16), Koerte (15), Tilmann (21) in Germany and Austria, Harvey Cushing (9), Frazier and Spiller (13), Keen, Tynlor, Elsberg, Beck (6), Adson, Lillie Learmonth, in America and Faure in France.

Improvement in technique and selection of better nerves rapidly advanced so that today we are witnessing the very best results that can ever be expected in the realms of anastomosis in the surgical treatment of facial paralysis.

By the brilliant efforts of these and many others along similar lines, it has been definitely demonstrated that a successful anastomosis of a neighboring nerve to the facial nerve can restore the contour of the face in repose, and by education can to a limited extent, bring about voluntary controlled facial movements. The nerves at first employed were the spinal accessory, the descendens noni, the hypoglossal, the glossopharyngeal.

It was discovered too, that, with a few exceptions, the hypoglossal was more satisfactory than the spinal accessory, that, in turn, the glossopharyngeal was better than the hypoglossal. While improvement in the technique of these various anastomoses brought about better functional results it was nevertheless noted that there remained two adverse factors to be considered. First, the

Fig. 8. In repose, three months later

Fig. 9. Showing emotional response, three months later

inevitable associated movements marred the results and, second, even in the most successful cases there was an entire lack of emotional expression. And emotional expression as we all know is a very important element in the daily contacts of a human being.

In these circumstances surgeons were still dissatisfied. In 1930 Sir Charles Ballance invited me to collaborate with him in an effort to improve the method of operative treatment of facial palsy. Aided by generous contributions from four foundations and a few

personal friends, we constructed an animal laboratory at my country place where we carried out our experiments. The result of our work presented to the American Otological Society in June, 1931 was published in the *Archives of Otolaryngology* (2).

We carefully and conscientiously repeated all the anastomosis operations here mentioned. We added anastomosis with sensory nerves which was successful in restoring facial control marred by no associated movement.

But motor restoration by this method remained slow and incomplete and again we were confronted by the fact that there was no emotional restoration. Gradually we evolved the idea that a direct repair might overcome these deficiencies. Hence we employed autoplasmic grafts—bridging the gap from the proximal to the distal segment of the divided facial nerve with grafts from the following nerves: (1) reversed facial, (2) external respiratory (Bell's), (3) intercostal, (4) descendens noni, (5) median cutaneous of the arm, and (6) great auricular.

In a large series of animals we were uniformly successful in restoring the facial function by introducing grafts taken from either motor or sensory nerves. Moreover we demonstrated that we might use a graft of any length, reversed or unreversed according to the demands of circumstances. Nevertheless in reporting the results of operations on these animals, we could make no categorical statement with regard to restoration of emotional expression. As far as we could judge, emotional expression of the comparatively limited nature exhibited by primates and cats was unimpaired, but not until we could operate for the benefit of humans could we be satisfied that this method of repair would meet all their higher requirements for the nuances of emotional expression.

I wish to state here that this is by no means an entirely new idea. It has long been known that the function of a divided nerve might be restored by the introduction of a graft into the gap, it has been employed in the soft parts for many years. Success moreover, has followed upon the use of grafts in other regions much longer than any which could ever possibly be required in the repair of an injured

facial nerve. The reason that it was not long before attempted was clearly because the facial nerve in its course through the temporal bone is enclosed in a bony tube of ivory like density.

The idea of repair within the temporal bone had already been suggested by Ney (20), Martin (19), and Bunnell (7). As a matter of fact the very idea of employing a long graft from the sural nerve was suggested by Dr. Bunnell, of San Francisco in 1925. I have since learned that he actually employed such a graft in 1930 and that the operation resulted in partial recovery of facial function which is still improving. However, we were quite unaware of his work until it was called to our attention after the publication of our paper (2).

The accompanying pictures taken from moving picture films made of 3 cases selected from a series of 13 cases, illustrate a wide variety of intratemporal repairs.

The first was a baby who suffered an accidental removal of 27 millimeters of facial nerve. This was repaired by a graft from Bell's anterior respiratory nerve 48 hours after operation (Figs. 1, 2, 3).

The second was an adult patient. In this instance 30 millimeters of nerve was accidentally removed in the course of a radical operation. Repair was done 11 months after injury. Bell's anterior respiratory nerve, 30 millimeters, was excised and immediately transplanted (Figs. 4, 5 and 6).

The third film was made of a child who suffered an injury of the nerve by fracture and compression of the fallopian canal. The nerve was uncovered and the sheath was slit over an area of 10 millimeters. Decompression only was done. No graft was necessary (Figs. 7, 8 and 9).

With these and a number of other successes which I reported at the annual meeting of the American Laryngological, Rhinological and Otological Society (2) I believe that a method of dealing with facial palsy has been presented, which offers sufficient improvement over the methods of anastomosis of the facial with other nerves to warrant the discontinuance of that method except in very rare instances.

However often while contemplating the manner of progress and the varying speed of improvement at different stages of the recovery in both animals and humans, certain phenomena kept obtruding themselves into my thought arousing three questions for solution

First, why in all the grafted cases, was there a long period of inactivity followed by a beginning slight response in the muscles and then, directly after this a rapid—almost tumultuous—improvement?

Second why did this same phenomenon occur when the ends of a freshly severed nerve were simply brought together with no intervening graft i.e. the same relative period of delay followed by beginning recovery and then tumultuous recovery—even though the actual elapsed time from injury to recovery might have been much shorter?

Third why when the graft was interposed did the length of time of the delayed response vary according to the length of the graft? Why after faint response first appeared, did the subsequent tumultuous—final complete—recovery take place in about the same added time in all cases regardless of whether the previous delay had been of short or long duration?

Now the answer to all these queries is to be found in the stupendous and splendid research in nerve degeneration and regeneration which has been going on for 40 years. Even earlier than this as far back as 1873 Létiévant (17) had done some work on the union of nerves which stimulated Ranvier (8) and Vulpian (8) Forreman (8) Ballance and Stewart (4) in this research. Then came a host of ardent workers, each adding much to the knowledge of the subject which, in its very nature presented almost insuperable difficulties (8).

There developed two schools whose disciples agreed as to *what* took place—but *not* as to *how* it took place. The contestants have some of them been calm and open minded others belligerent and unyielding.

Leaving out of the question for the moment *how* it takes place, *what* takes place is that a divided nerve suffers a traumatic degeneration for a short distance in the cut ends of both its proximal and distal segments. There is a slight difference in the two segments in this traumatic degeneration owing to the fact that the proximal segment is in direct communication with the so called trophic influences emanating from the central station, and, as a consequence, its wires or axons—or

whatever you choose to call them—do not degenerate except for a short distance proximal to the place in the nerve trunk where the trauma has occurred.

The proximal axons multiply and try to push on out into the distal space hoping to make some connections, and do some work again. Many of these, failing to make connections turn back—get "balled up" so to speak hence the so called bulbous end of the proximal segment.

Now the distal segment undergoes a similar traumatic degeneration of the cut end which is necrotic in character, but, having no connection any longer with the central trophic influences it makes no effort to function there is no multiplication of axons no bulbous end. In addition to this traumatic degeneration it undergoes another form of degeneration throughout its whole extent right down to the terminal end plates, which transmit the nervous force to the muscle fibers.

This is called wallerian degeneration. What is wallerian degeneration? It is a very definite complicated process which begins at once in the distal segment of a nerve when it is cut off from its central station at any point. This may take place by a squeeze from toxic poisoning or inflammatory swelling as in Bell's palsy or by actual division as in accidental trauma. When this happens, every last nerve cell in every axon disintegrates and finally disappears leaving a system of tracts or tubes called bands of Büngner.

Now the question of how this takes place has caused a great deal of strife and difference of opinion. Volumes have been written about it. Suffice it to say that "digestive ferments," "enzymes, chemical or electrical influences, bring about a granular and fatty degeneration resulting in a mass of detritus in these tubes which, by invasion of phagocytes from the blood stream is taken up and removed, finally leaving the cleared out tubes. These tubes then contain no nervous elements capable of transmitting nerve impulses. They are past that possibility when response to faradic stimulation ceases. In time these pathways are completely vacated and made ready to receive new axons from the proximal segment if they are permitted to enter.

What's to prevent them? Pus, fat, muscle, toxic products, foreign bodies leucocytes, lymph in the scar. Do any of these impediments succeed in stopping all axons? Certainly not! Usually a few get by every obstacle but not in sufficient numbers to bring back muscular function.

When free passage is provided they "shoot through" with incredible speed and eventually many of them form connections with the terminal end plates in the muscle fibers.

The degenerative process in the distal segment goes on for several weeks. The main part of it however is accomplished in 2 or 3 weeks. There is a time when the remaining products of degeneration in the distal segment are supposed to have a "chemotactic action"—a "come hither"—an "attraction" for the axons of the proximal segment. They are supposed to orient them to exert a *ris a fronte* from the distal segment aiding the *ris a tergo* from the proximal segment. This chemotactic influence is supposed to be at its best about the end of the second week.

This observation was made by Ottorino Rossi who published an account of some clinical work he had done in Man quoted by Cajal where he says (8) the ideal graft is the peripheral stump with bands of Buengner, newly taken from the animal operated on, 8 to 15 days after the operation. The newly formed fibers travel through it with an extraordinary speed deviations and retrogressions being very much diminished. In order of effectiveness there then follow grafts of fresh nerves without bands of Buengner, and finally normal nerve segments which are preserved in a physiological salt solution under aseptic conditions' (Tello).

However the larger the animal and the larger and older the nerve the longer the degenerative process takes. My own experiments on rhesus monkeys lead me to think that it takes about 3 weeks to clear the tracts sufficiently for the best clinical results.

At any rate, this process of clearing out of the tubes in the distal segment of a divided nerve takes place through the combination of chemical and circulatory influences very actively for a period of from 2 to 4 weeks, and continues less actively for a much longer

time. And here one finds the answer to my questions about grafts.

When a nerve is divided and immediately reunited there follows a period of "hesitation" before recovery begins to be manifest, because this wallerian degeneration in the distal segment must take place and the paths be at least partially cleared before the new axons from the proximal segment can travel through. A fresh graft excised from another nerve is crowded with nerve cells which must "degenerate" and be cleared out in the same manner before new axons can pass through. This process when the nerve graft is immediately transplanted, must be accomplished with the handicap of no circulatory apparatus at first and only a poor one for some time. The graft must live on the fluids in which it is bathed and which are exuded from surrounding tissues, until it finally develops a circulatory system of its own.

In the meantime the whole distal segment with its undisturbed circulation has gone through wallerian degeneration rapidly. Then, when the transplanted graft is finally cleared out sufficiently so that the axons from the proximal segment no longer impeded have pushed on through it they are "received with open arms" at least with open tubes by the distal segment. Hence the long delay while the graft is being traversed, finally followed by signs of slight improvement as some axons reach their terminal connections, and then "tumultuous" improvement as hundreds of others do the same.

Then, why will not cutting the nerve selected for graft material and allowing the distal segment to degenerate for the proper time in its own environment with its undisturbed circulatory apparatus—just as happens in the distal segment of the facial—clear out the tubes and render a graft which has been excised from it almost equal to the degenerated distal segment of the facial as a conveyor of axons?

I have tried the plan on a number of rhesus monkeys and it works. I have "prepared" the anterior femoral cutaneous and the great auricular in this way. Degeneration has been allowed to take place for from 10 to 35 days. The protocol of the experiments follows.

PROTOCOL OF THE EXPERIMENTS

Anastomotic nerve grafts—"prepared by degeneration *in situ*"

Controls—fresh grafts

1. The anterior femoral cutaneous nerve

Single strand

Experiment 3—rhombus No. 8

Experiment 5—rhombus No. 6

Experiment 7—rhombus No. 7

Double strand

Experiment 1—rhombus No. 10

Experiment 2—rhombus No. 8

Experiment 4—rhombus No. 9

Experiment 6—rhombus No. 11

Two strands

Experiment 6—rhombus No. 6

The great auricular nerve

Single strand

Experiment 9—rhombus No. 13

Experiment 11—rhombus No. 14

Experiment 12—rhombus No. 15

Three strands

Experiment 9—rhombus No. 13

Experiment 13—rhombus No. 16

Control

1. Experiment

2. Experiment 9

In situ plastic nerve grafts. The nerves employed in these experiments were (1) the anterior femoral cutaneous nerve and (2) the great auricular nerve.

A *Control* graft, freshly excised from another nerve was immediately placed in the gap between the proximal and distal segments of a divided facial nerve. Varying lengths of gap determined by removal of segments of varying measured lengths of the facial nerve.

A graft from the distal segment of a similar nerve which had been previously "prepared." By "preparation" we mean that the nerve was divided. The distal segment was then left, undisturbed by dissection, in its own bed, for varying periods while it underwent wallerian degeneration, in exactly the same manner in which the distal segment of a facial nerve degenerates after division or injury.

These grafts, used as paths to convey axons from the proximal to the distal segment of the divided facial nerve are taken from nerves which have undergone varying periods of degeneration to determine if possible at what stage of this degeneration they will prove most attractive to the axons, or at least, present the minimum obstruction to their *en masse* passage.

Note.—In series of eleven monkeys the function of the facial nerve was abolished either by division, resection, or section of alcohol within the sheath, thereby causing immediate facial palsy as evidenced by loss of all voluntary emotional, or reflex action. The distal segment was stimulated with the faradic current, at 10-20 hour intervals, to determine when synaptic response disappeared. (Wallerian reaction of degeneration.) In 8 it disappeared in 12 hours, in 1 it disappeared in 40 to 72 hours, in 1 it disappeared in 96 hours. In response persisted 9 days.

Experiment 1—rhombus No. 10, control.

45 hours. Complete loss of response in muscles of face to faradic stimulation. A double strand of the anterior femoral cutaneous nerve, 3 millimeters, inserted in gap.

44th day. Farist response to strong faradic stimulation in muscles of upper lip.

45th day. Farist response to strong faradic current in upper and lower lips.

53rd day. Farist response in nose and lips.

70th day. Facial tic in muscles around the mouth greatly aggravated by faradic stimulation or conjunctival irritation. Winking reflex on threat and conjunctival irritation.

77th day. Tic very evident, no voluntary movements.

80th day. Response in muscles of lips to weak faradic current. Farist response in all muscles of face to strong faradic current.

95th day. Facial tic marked when animal is tied to table, violent on conjunctival irritation or faradic stimulation.

Note.—Difficult to differentiate between response to faradic stimulation and tic, as animal makes some responses when stirred up by stimulation on normal side.

121st day. Facial tic still marked. Response to strong faradic current in all muscles.

The tic is interesting in connection with the series of immediate grafts and various anastomoses recounted by Sir Charles Ballance and myself in our experiments reported in 1931 (*Arch. Otolaryngol.* 1932 Jan.)

Experiment 2—rhombus No. 8.

96 hours. Complete loss of response to faradic stimulation in muscles of the face. A double strand of the anterior femoral cutaneous nerve was prepared 10 days, 15 millimeters, and inserted in the gap.

120th day. Farist response to strong faradic stimulation in the muscles of upper and lower lip. Tests at 2-day intervals showed only weak response in the same muscles up to the 43rd day.

43rd day. Distinctly better response in all the muscles around nose and mouth. Farist response around eye.

40th day. Distinct improvement evident in all muscles.

55th day. Active response to weak faradic stimulation in all muscles.

57th day. Still improving: conjunctival reflex and threat reflex present.

61st day. Shows quick response in all muscles—voluntary and emotional responses very evident.

75th day. Very marked progressive improvement.

Experiment 3—rhombus No. 8.

45 hours. Complete loss of response to faradic stimulation in muscles of the face. A single strand of the anterior femoral cutaneous nerve, prepared 10 days, 7 millimeters, was inserted in the gap.

17th day. Weak response to strong faradic stimulation in the muscles of upper and lower lip and nose. Stimulation at 2 day intervals showed no definite change until

34th day. Definite response to strong faradic stimulation in all muscles of face.

42th day. Response to weak current around mouth, and to strong current in all other muscles.

55th day. Response to weak current in all muscles: conjunctival and threat reflexes to eye muscles; spontaneous movements.

73rd day. Marked progressive improvement.

85th day. Active conjunctival and threat reflexes. Farist response to weak current in all muscles. Facial tic in lower muscles of face: observed when animal is agitated and greatly aggravated by conjunctival irritation and faradic stimulation.

126th day. Facial tic still present. Response to weak faradic current improved in all muscles.

Experiment 4—rhombus No. 9.

48 hours. Complete loss of response in muscles of face to faradic stimulation. A double strand of the anterior femoral cutaneous nerve prepared 11 days, 10 millimeters, was inserted in the gap.

14th day Faint response to strong faradic stimulation in muscles of upper lip and nose.

30th day Definite response to strong current in all muscles, conjunctival and throat reflexes in eye spontaneous movements.

32nd day Unfortunately the animal died from the anæsthetic. It was the most promising case in this series.

Experiment 5—rhesus No. 11

65 hours. Complete loss of response in muscles of face to faradic stimulation. Single strand of anterior femoral cutaneous nerve prepared 10 days, 6 millimeters, inserted in gap.

30th day Faint response to strong faradic stimulation in muscles of upper and lower lips. Tests at 43 hour in intervals for following 16 days showed no definite change.

43rd day Response to weak current in muscles around mouth and nose, to strong faradic current in muscles of face.

57th day Conjunctival and throat reflexes in eye spontaneous movements.

62nd day Marked improvement in all muscles of face.

68th day Progressive improvement.

76th day Fair response to weak faradic current in all muscles. Active conjunctival reflex. Facial tic in lower muscles of face.

90th day Associated tic still marked on conjunctival irritation or faradic stimulation. Good response to strong faradic current.

111th day Tic appears less evident. Muscular responses to faradic stimulation decidedly improved.

Experiment 6—rhesus No. 16

63 hours. Complete loss of response in muscles of face to faradic stimulation. Two strands anterior femoral cutaneous nerve, prepared 12 days, 7 millimeters each, were inserted in the gaps first to auriculotemporal which had been accidentally divided second to main branch.

36th day Faint response to strong faradic stimulation in muscles of upper and lower lips.

38th day Distinct response in all muscles of face to strong faradic stimulation.

45th day No marked change.

70th day Distinct response in muscles of upper and lower lips to weak faradic stimulation. Response in all muscles of face to strong faradic stimulation.

81st day Conjunctival and throat reflexes in eye muscles. Facial tic in lower muscles of face—exaggerated by conjunctival irritation or faradic stimulation. Response in all muscles of face to weak faradic current.

87th day Tic not as regular or as strong. All muscular responses rapidly improving.

Experiment 7—rhesus No. 17

73 hours. Complete loss of response in muscles of face to faradic stimulation. A single strand of the anterior femoral cutaneous nerve, prepared 21 days, 12 millimeters was inserted in the gap.

36th day Faint response to strong faradic stimulation in upper and lower lips.

37th day Faint response to strong faradic stimulation in muscles of upper and lower lips, and around nose.

51st day Response in all muscles of face to strong faradic current.

65th day Conjunctival and throat reflexes present. Facial tic appeared in lower muscles of face. Response in all muscles of face to weak faradic current.

73rd day Conjunctival reflex active. Facial tic exaggerated by throat, irritation of conjunctiva, or faradic stimulation. All muscular responses were improving.

70th day Facial tic not as regular or as strong. Muscular response to faradic stimulation improving rapidly.

Experiment 8—rhesus No. 18.

213 hours—0 days, 2 hours. Complete loss of response in facial muscles to faradic stimulation. A double strand of the anterior femoral cutaneous nerve, prepared 35 days 8 millimeters, was inserted in the gap.

16th day Faint response to strong faradic stimulation in all muscles. Weak conjunctival reflex no throat reflex.

23rd day No marked change.

51st day Conjunctival reflex incomplete. Response in all muscles to strong faradic current improved. Weak faradic current causes response in muscles of upper and lower lips and nose.

90th day Active conjunctival reflex. Facial tic in lower muscles of face. Response in all muscles of face to weak faradic current. Stimulation and conjunctival irritation exaggerate facial tic.

105th day Facial tic decidedly less evident. Fair response in muscles of face to weak faradic current.

Experiment 9—rhesus No. 12. Control

45 hours. Complete loss of response in muscles of face to faradic stimulation. Three strands of the great auricular nerve, 5 millimeters, was inserted in the gap. Stimulation with faradic current at short intervals gave no response in muscles of face until the fifty first day following repair.

51st day Weak response in all muscles to strong faradic stimulation. Faint conjunctival and throat reflex. A definite tic of the risorius at irregular intervals varying from a few seconds to a minute. The tic is exaggerated by faradic stimulation or conjunctival irritation.

64th day Faradic response much more definite the tic is still present.

70th day Conditions same as on sixty-fourth day.

91st day Faint response in all muscles of the face to strong faradic stimulation. Tic is so aggravated by stimulation that it is difficult to differentiate response to faradic stimulation from tic. Good conjunctival and throat reflexes.

110th day Facial tic continues *pari passu* with improving muscular responses. Response to faradic stimulation improving.

Experiment 10—rhesus No. 13

45 hours. Complete loss of response in muscles of face to faradic stimulation. A single strand of the great auricular nerve, prepared 10 days, 6 millimeters, was inserted in the gap.

48th day Faint response to strong faradic stimulation in muscles of upper and lower lips.

54th day Definite response to strong faradic stimulation in all face muscles. Conjunctival and throat reflexes.

61st day Definite tic in the risorius aggravated by faradic stimulation or conjunctival irritation.

67th day Same reactions.

81st day Facial tic increases when animal is restrained, also exaggerated by faradic stimulation or conjunctival irritation. Active conjunctival reflex. Voluntary movements. Excellent response in all muscles of face to strong faradic stimulation.

93rd day Facial tic still marked. Fine response in all muscles of face to weak faradic stimulation.

100th day Facial tic not so marked. All muscular responses steadily improving.

Experiment 11—rhesus No. 14.

47 hours. Complete loss of response in muscles of face to faradic stimulation. A single strand of the great auricular nerve, prepared 11 days, 7 millimeters, was inserted in the gap.

38th day Faint response to strong faradic stimulation in upper and lower lips.

41st day Response also in muscles of nose.
58th day Response to strong faradic stimulation in all muscles of face: a definite tic in the risorius, conjunctival and throat reflexes. The exaggerated by faradic stimulation and conjunctival irritation.

69th day All responses more definite the remains.

79th day Vigorous response in all muscles of the face to strong faradic stimulation. Tic aggravated by rostralist.

107th day Fine response in all muscles of face to weak faradic stimulation. Tic remains but seems less regular.
Experiment 12—rhizoma No. 27.

7 hours Complete loss of response in muscles of face to faradic stimulation. A single strand of the great auricular nerve, prepared 21 days, 8 millimeters, was inserted in the gap.

17th day Faint response to strong faradic stimulation in muscles of upper and lower lips.

26th day Response to weak faradic stimulation in muscles of upper and lower lips. Response to strong faradic stimulation in all muscles of face.

33rd day Responses in all muscles improving.

61st day Fair response in all muscles of face to weak faradic stimulation.

Experiment 13—rhizoma No. 26.

96 hours Complete loss of response in muscles of face to faradic stimulation. Three strands of the great auricular nerve, prepared 2 days, 7 millimeters, were inserted respectively in gaps as follows: (a) from the proximal segment to the temporal branch, (b) from the proximal segment to the cervicofacial branch, (c) from the proximal segment to the buccinator branch.

16th day Faint response to strong faradic stimulation in muscles of upper and lower lips.

25th day Slight response to weak faradic stimulation in muscles of upper and lower lips. Response in the risorius to strong faradic stimulation.

32nd day Definite response in all muscles to strong faradic stimulation.

54th day Tests made at short intervals showing responses to faradic stimulation improving.

60th day Conjunctival and throat reflexes present. Facial tic appeared in lower muscles of face. Aggravated by conjunctival irritation and faradic stimulation. Muscular responses to weak faradic stimulation in all muscles of face.

You will notice, on reading the protocol, that the muscular responses where the "prepared" grafts were used were obtained in a quarter to half the length of time required to obtain similar responses in the controls, where fresh grafts were used.

It would seem, from a study of these experiments so far as they have gone that when autoplasmic nerve grafts are employed to bridge gaps in a divided facial nerve better results—both as to speed of recovery and more nearly normal restoration of function—may be expected if the graft material is "prepared" by division and degeneration of the nerve in situ.

It is safe to say that any graft which has been taken from a nerve "prepared" from 2 to 4 weeks will probably be much more efficacious than a fresh graft. While any desired nerve may be so "prepared" and employed I believe that the anterior femoral cutaneous is the best.

I have as yet used only fresh grafts in ten humans. I am now "preparing" the anterior femoral cutaneous which I propose to use, after 3 weeks degeneration, in 2 cases of accidental palsies following mastoid operation, 1 of 4 years duration and the other of 4 months duration.

I believe that direct repair by transplantation of autoplasmic grafts either freshly excised or prepared as I have indicated will supplant the method of anastomosis in all except the rare cases in which the facial palsy has been caused by intracranial injury or disease.

FEBRUARY 1933

THE 1932 CLINICAL CONGRESS IN ST. LOUIS

THE twenty second annual Clinical Congress of the American College of Surgeons held in St. Louis October 17-21, 1932—the first Clinical Congress held in that city—will be remembered as an outstanding success by reason of the large attendance, the widespread enthusiasm, a clinical program of exceptional merit and broad scope and a series of scientific meetings and conferences that brought to the attention of the profession many notable contributions. A highly interesting program of operative clinics and demonstrations in thirty hospitals and two medical schools that embraced all phases of general and special surgery organized by the Committee on Arrangements under the leadership of Dr. Everts A. Graham chairman was presented during the five-day session and received enthusiastically by the 2,000 visiting surgeons.

In the departments of ophthalmological and otolaryngological surgery special plans for the entertainment of the visiting surgeons resulted in a comprehensive clinical program emphasizing the important research work being done in

St. Louis institutions. At two evening sessions eminent specialists in these fields presented important and timely papers to large and appreciative audiences.

Four symposia presented at the afternoon sessions were outstanding features of the Congress and provided a number of notable contributions to our surgical knowledge. These symposia included (1) "Cancer is Curable" with reports on five year cures of different types of cancer by thirty eminent specialists in the various surgical fields, (2) "Treatment of Fractures" participated in by a group of surgeons of wide experience in this special field, (3) "Industrial Medicine and Traumatic Surgery" with papers and discussions dealing with the clinical and economic aspects of this important field and a report of last year's survey of American industries by representatives of the College, (4) "Teaching of Surgery and the Surgical Specialties" which included a discussion of methods recommended for graduate and undergraduate instruction. The papers presented appear in this issue.

The program for the evening meetings planned for audiences of varied interests, presented a group of papers of exceptional worth contributed by men of high standing in various fields of surgery. They attracted large audiences that crowded the ballroom to capacity. At the presidential meeting on Monday evening the retiring president Dr. Allen B. Kanavel of Chicago, in speaking on the "Intangibles in Surgery" found in the philosophy and history of surgery the proper foundation on which to build for higher ideals. Dr. J. Bentley Squier, of New York, inaugurated as president, delivered an address dealing

definitely with the Fundamentals of Specialism. Sir William I DeCourcy Wheeler of Dublin, Ireland past president of the Royal College of Surgeons of Ireland presented for the John B. Murphy oration in surgery an interesting talk on Pillars of Surgery.

A symposium on thoracic surgery, another on intestinal surgery, together with a group of papers dealing with other surgical and gynecological subjects were interesting features of the meetings on Tuesday, Wednesday and Thursday evenings. The papers, by speakers from outside St. Louis with wide experience in their special fields, were short and well presented with the use of many illustrations. These were discussed by local clinicians. In all of these the clinical aspects were especially emphasized, bringing to the members of the Congress many new ideas and added inspiration. The papers are published in this issue.

The beautiful ceremonial of the Convocation on Friday evening attracted an audience that filled the ballroom of the Jefferson Hotel to overflowing. A class of 633 new Fellows, coming from forty-three states, two provinces of Canada, and six foreign countries were admitted into fellowship in the College. Honorary fellowships were bestowed on two distinguished visitors: Sir George Lenthal Cheate, London, England, and Dr. José Goyanes, professor of surgery in the National Academy of Medicine of Madrid, Spain.

In his presidential address, Dr. Squier reviewed in detail the accomplishments of the College during twenty years and contributed suggestions as to its future activities. The fellowship address by Professor Robert A. Millikan, director of the Norman Bridge Laboratory of Physics, California Institute of Technology, gave a highly interesting presentation of Some New Things in Physics.

An audience of 10,000 attended the Community Health Meeting on Wednesday eve-

ning, crowding to its limit the gymnasium of St. Louis University and overflowing into and filling to capacity the auditorium of the law school of the same university. It was estimated that in addition 10,000 people were turned away, unable to gain admittance to either of these halls. Twelve speakers presented to this vast audience the aims and objects of the American College of Surgeons, told of the contribution of scientific medicine to the progress of the civilized world, described modern hospitals, spoke of specific diseases and their symptoms, such as cancer, appendicitis, backache, nervousness, etc. These vast audiences evidenced the avidity on the part of the public for reliable information on matters pertaining to personal health—ample justification for the continuance of the College's educational program under which community health meetings have been held in 111 cities of the United States and Canada since 1920. As a part of the program, health talks were given in St. Louis by speakers for the College to the students of ten high schools, members of twelve clubs, and a vast invisible audience through fifty-seven radio broadcasts.

The annual hospital standardization conference, with a four-day program, presented many valuable discussions of vital problems concerning administrative and professional matters with emphasis on hospital economics. A unique feature was carried out on the closing day—the presentation in two hospitals of a series of practical demonstrations in hospital administration. A summary of the results of the conference would include: (1) A better appreciation of standardization principles and their practical application, (2) a clearer understanding of the hospital's internal and external relations, (3) a further contribution to our knowledge of the application of business methods as a means of meeting present-day economic problems.

A well organized and adequately manned press bureau worked in close co-operation with the local newspapers and the great international press associations to provide an adequate report of the proceedings of the Congress. Recognizing the importance of such a gathering and the opportunity for the dissemination of news of important advancements in medical science, out of town newspapers sent special representatives. The result was that the press of the country at large carried each day comprehensive and well written articles that reflected credit upon the College and its accomplishments.

CONFERENCE ON CURABILITY OF CANCER

WHEN thirty of the eminent surgical specialists of the country assembled and tell of their cases of cancer that have lived five years and more following treatment, the total of their successes assumes a proportion that must give renewed stimulus and confidence to the surgeon justification for increased hope on the part of the patient with cancer decision to apply for early treatment when cancer is suspected, and a brighter general outlook for the future in the cancer field.

The conference on the Curability of Cancer held during the 1932 Clinical Congress of the American College of Surgeons must perforce produce such results. Surely the more than thirty thousand added years of health represented by the reports (of their own cases) given by these surgeons must command the attention of one attempting to appraise the value of the work of the medical profession. This is no exaggeration, for the average duration of life in untreated cancer cases is usually estimated at two and one half years, and the four thousand three hundred forty four patients reported by these sur-

geons are known to have lived in good health from five to thirty years following treatment.

Some of the speakers at this conference presented good and valid reasons why the interest of the medical profession in the advanced cases of cancer should be increased. Occasional unexpected responses to therapy and the relief that can be afforded to the majority of these patients by surgical, radiological, or medical palliative measures urgently bespeak an active and confident attitude on the part of the medical profession toward the late cases of cancer.

While it is well known that cancer on the superficial parts of the body as a rule is recognized at an earlier stage and therefore gives better statistical results, in a survey of the program of this meeting the attention is captivated by its inclusiveness which demonstrates the successful application of therapeutic methods even to those parts of the body which are the most difficult to approach.

Another interesting phase of this conference was its forceful refutation of the alleged soullessness of the modern clinic. The introduction of accurate records, and of complete follow up data, which are made possible by the utilization of social service workers, has made it possible for the surgeon to maintain close supervision of his patient and to know the condition of that patient over periods up to thirty years.

It is hoped that one result of this conference will be the stimulus offered to the medical profession to make use of the methods of diagnosis and treatment which have been shown to be successful, and by earlier and more effective application of these methods, to other cancer cases to increase manifold the number of cures of this disease.

ROBERT B. GREENOUGH
BOWMAN C. CROWELL.

PRESIDENTIAL MEETING, CONVOCATION

ADDRESS OF WELCOME¹

EVARTS A. GRAHAM M.D., F.A.C.S., St. Louis, Missouri

ST LOUIS is pleased to welcome the Clinical Congress of the American College of Surgeons. We hope that this first visit to this city will prove interesting and pleasant enough to warrant a return. To many of our eastern friends the Mississippi River still marks the edge of the frontier as it did at the time that Lewis and Clark started from here on their famous expedition to explore the Northwest Territory. We hope however that after the week of medical activities no one will feel that St. Louis is still a frontier town in a medical sense despite its location on the western side of the Father of Waters. The two medical schools and the many fine hospitals feel that they can be justly proud of their accomplishments. St. Louis was one of the first cities of the country to develop modern university medical education and the standards and methods estab-

lished here have served as models to many of the more recent extensive educational developments in other parts of this country and to some extent in other countries. Although the realization of our plans has not been completed—in fact no scheme of education can ever properly be considered completed—we invite you to join with the group of visitors from all parts of the world interested in medical education who have come here to investigate at first hand what we are attempting to accomplish. St. Louis is said to be a city surrounded by the United States. It is not Eastern, Western, Northern, or Southern. It has perhaps some of the attributes of all sections of the country. We like to think that from the South we have taken over the characteristic feature of hospitality and I hope that this good side of us will be in evidence this week.

¹Presented before the Clinical Congress of the American College of Surgeons, St. Louis, Missouri, October 7-12, 1933.

INTANGIBLES IN SURGERY¹

ALLEN B. KANAHEL, M.D. F.A.C.S., CHICAGO

IN our commendable endeavor as an organization to elevate the practice of surgery we may well pause to consider if in our emphasis upon technical training, standardization of teaching and practice, and study of economic factors in medicine, we are not overshadowing the intangible qualities that have made surgery a growing science and an increasing art. An organism may be perfect anatomically but it needs the elusive spark of life to give it being. Ideals, self-sacrifice, personal and professional honesty, love of the search for knowledge, culture, judgment, common sense, and imagination may not be ponderable but nevertheless their presence marks difference between technical efficiency and greatness.

In this day of commercialism, political crassness, and Freudian complexes, the ideals and as-

pirations of the physician and scientist come as a breath of fresh air in a musty room. The commercial world exalts those who accumulate wealth, the political deifies the narrow minded nationalist and the unthinking citizen finds his hero in the banalities of the moving picture theater. Medicine engrossed in scientific investigation and its application to the relief of human suffering reserves its insignia of greatness for those who find their satisfaction in service and in the search for the elusive secrets that benefit mankind.

The American College of Surgeons was founded upon the ideal of disinterested service. The permanent accomplishments of the College depend upon the measure of devotion of each fellow to this basic principle. This ideal is a part of our heritage. Guy de Chauliac, the father of surgery

Address of the Elected President, presented before the Clinical Congress of the American College of Surgeons, St. Louis, October 17, 1933.

said the surgeon should be "modest, dignified, gentle and merciful, not covetous nor an extortionist of money, rather let his rewards be according to his work, to the means of the patient to the quality of the issue and his own dignity." Paracelsus, two centuries later, said that the "physician shall study daily and learn from the experience of others. He shall at all times be temperate, serious, chaste, living rightly, and not a boaster. He shall consider the necessity of the sick rather than his own, his art rather than his fee."

The unthinking public, accepting its opinions ready made from the tabloid newspaper, the smoking compartment of the Pullman, and tea-cup gossip, presumes to judge the qualifications and standing of the physician. The clever carpenter in surgery, the facile adaptor of diagnostic principles, and the self-confident therapist may attain an ephemeral eminence but the calm, flowing and relentless stream of time leaves standing only our Pasteurs, Listers, and Hunters—our idealists, unbiassed with self-sacrifice, honesty, industry, learning and gifted with judgment and imagination. The men we honor go their way with equal happiness in daylight and darkness, sacrifice comfort, home, and even life itself in their devotion to their chosen calling. Mawkish sentimentalists bewail the laboratory use of animals that has saved tens of thousands of human lives but forget that the physician has been just as willing to use his own body as a human test tube or culture medium, that Senn transplanted to his own body cancer cells to disprove their transmissibility, that Lazarus by the loss of his life demonstrated the cause of yellow fever and that Ricketts by a similar sacrifice proved the source of typhus fever.

Incappable honesty in scientific investigation and in our relations to patients and the community must be the foundation of our work. No surgeon can be truly great if he deceives himself or the public. He should never administer treatment except after painstaking study of the patient, his disease and his bodily resistance, and only after he is convinced that he would accept the same advice for himself or his family. He should not undertake surgical intervention unless he is competent to treat not alone the specific condition attacked but also any complications that may arise. Any operation performed at the request of colleagues without personal study and justification shows not only intellectual laziness, but culpable acquiescence. Those who would barter their inheritance of disinterested service for money or let it influence their judgment should

not forget that Judas thirty pieces of silver bought only a potter's field.

The little surgeon hastens to report his successful experiences, the great surgeon is more concerned with his failures. Sims reported twelve failures on a single patient before he discovered the principles of the treatment of vesicovaginal fistula. Fenger was as careful to publish the fact that the first six patients upon whom he performed hysterectomy died, as he was to present his great work on stones in the common bile duct. Mott did not fear to announce a fatality from his first attempt to ligate the innominate artery. These men had good precedent, however, for of the forty-two clinical cases reported by Hippocrates, sixty per cent had a fatal termination. "I have written this down deliberately," says Hippocrates, "believing it as valuable to learn of unsuccessful experiments and to know the cause of failure."

The great surgeon, in common with all scientists loves to wrest from nature its secrets for the pure joy of increasing knowledge. He may be oblivious of its immediate application but he is confident of its ultimate benefit to mankind. Franklin's apt rejoinder "what is the use of a baby," to a critic of pure scientific investigation is a complete answer to those who demand immediate results from such studies. Ramsey and Rutherford discovered invisible gases by using a microbalance that would detect a difference in weight of one-fourteen billionths of an ounce, and by substituting one of these for nitrogen helped to prevent the "bends" in caisson workers. Dalton made two hundred thousand observations on the atmosphere and in studying the composition of air, arrived at the atomic theory. Resting on Dalton's assumption, Priestley obtained pure nitrous oxide and Davy discovered its physiological effects so beneficent in the practice of medicine. Insulin, adrenalin, toxins and anti-toxins, asepsis and antiseptics, all surgical and medical procedures, have back of them a dim but glorious procession of physicians and investigators who have devoted their lives to unraveling the tangle of nature. It is to these restless spirits of insatiable curiosity that medicine owes its debt, much more than to the facile adaptors of other men's ideas.

The physician must be industrious. He must submerge his life in his profession and the lives of his patients. Medicine is a jealous mistress. She brooks no rivalry with business, art, or social life. Gross wrote his great surgery while being driven about to make calls upon his patients. Ehrlich tried six hundred and five chemical combinations

before discovering salvarsan. The Cures searched through a ton of pitchblende to find a few crystals of radium. The great among us are driven by this dominating passion and are not content to whisper their *Vnus Dimittis*. Now let thy servant depart in peace, until they have added something of permanent value to the storehouse of surgical knowledge. This is not with the hope of immediate fame but with the laudable desire to be associated, even in a small way with the brilliant procession of physicians stretching back into dim antiquity who have enriched science and served humanity. Industry and knowledge beget modesty and few great surgeons could be psycho-analyzed as having a superiority complex.

A familiarity with the history of medicine and cultural literature is essential to the great surgeon. Hippocrates said: "An important phase of the practice of medicine is the ability to appraise its literature correctly." The trite expression "beacon lights of history" suggests the proper application of medical literature and history. It should warn us of the rocks and shoals to be avoided, indicate the clear channels of thought through which our course may be charted into the broad ocean of undiscovered knowledge where experiment, adventure into new waters of imagination may bring fruitful results. The mantle of Elijah does not fall upon the ignorant man. Culture safeguards our scientific studies, broadens our medical horizon, and gives joyous communion with the creative minds that have gone before. The surgeon cannot be truly great unless he loves literature, history and the cultural arts that stimulate, develop and enrich the inner man.

Narrow mindedness is the offspring of lack of culture and literary perspective. Productive experimentation is not blind chance but constructive hypothesis based upon knowledge. When Becher introduced the theory of phlogiston as an element of fire to explain burning, oxidation, and calcination—he retarded science for a century. It was theory without basic knowledge. Unfortunately we still repeat the same error in modern medicine. Our carpenter gastropexies, our short circuiting operations for gastropnoia advocated without physiological knowledge, and our abandoned drugs introduced by empirical rather than scientific methods, are not far enough from the bezoar stones, electrical belts, and the manipulations of the quack to save us from a measure of just criticism.

Judgment and common sense are inherent qualities, but they may be improved by thought and study. Not infrequently we see too ready acceptance of theoretical procedures and advertised

nostrums, operations advocated without adequate analysis of the dangers and complications, and surgical procedures instituted without due consideration of the resistance of the patient and the physiological result. The surgeon who rushes to introduce selective "free wheeling," "dual control," and the "high compression" motor into his practice is seldom the great leader of his profession. It is true that this ill advised haste more often arises from thoughtless enthusiasm than dishonesty, but it does show a lack of judgment. The use of new clinical procedures should be preceded by physiological study, their value verified by careful experimentation and their employment dictated by judgment and common sense. Our surgical highway is strewn with discredited diagnostic procedures, discarded anesthetics, and non-physiological operative procedures. We think of Pare as the imaginative surgeon but one has only to read the delightful description of his treatment of the compound infected fracture of the *Marquis d'Autret*, to realize that he was endowed with superlative judgment and common sense. In this day of futurists and cultists in medicine, as well as the arts, let us not forget that common sense is the basis of all good surgery.

Nothing vitiates judgment and common sense more than the tyranny of the fixed idea. The surgeon should not be a cinematographic automaton. Open-mindedness is probably the hardest quality to maintain. Several centuries ago Roger Bacon said the causes of human error were undue regard for authority, habit, prejudice, and the false conceit of knowledge. And Turgot, "It is not error that opposes the progress of truth. It is indolence, obstinacy, the spirit of routine and everything that favors inaction." The little surgeon with his fixed ideas institutes procedures cemented by authority or habit, cannot meet in a constructive way new or unexpected conditions, does his gastro-enterostomy for all ailments of the stomach, uses the same anesthetic for all cases, treats his fractures by the same routine method always, does the "Smith" or "Jones" operation in a given condition without having the pliability of mind or imagination to modify it to meet the varying conditions. All science suffers from this blight. Lavoisier's head had already fallen from the guillotine before Priestley acknowledged the possible truth that burning was the union of the consumed substance with oxygen. Berzelius' classic contribution upon nitrous oxide was refused publication by the Academy of Science because "they did not approve the new chemical nomenclature" of Lavoisier which he had dared to use.

Our institutions of learning too often teach standardized courses, foster the groove mind and find it difficult to encourage the genius in special lines. Berzelius, the Swedish chemist, was warned on his graduation day that there was no hope that he would do anything creditable since he had cut his Hebrew courses. Liebig was expelled from school with the statement that he was "hopelessly useless," because an explosion occurred while he was devoting his time to some original experiments with fulminic acid and John Hunter was the despair of his parents and teachers because he preferred to study nature in the woods rather than from books.

Imagination is the quality that raises us above mediocrity. It is not the peculiar attribute of the educated man. The Melanesians, before the advent of Cook, used the freshly cut and peeled branch of a tree as an intramedullary splint in fractures. The plaster cast had its origin in the practices of the African savage. To imagination science owes its progress. Avogadro had no balance to weigh his molecule, no microscope to see it, no chemical reaction to prove it. It was a pure fabrication of his brain but justified by the fact that it explained known facts and was the solid foundation for new conceptions. Mendelëff's periodic table of elements and Mosley's X-ray spectroscopic prophesy and proof of ninety-two elements, were imaginative conceptions resulting from an almost fanatic devotion to intense investigation. Langmuir's conception of the structure of the atom may one day make real the alchemist's dream of transmitting lead into gold. The imaginative scientist assumes majestic stature in comparison with those who follow meekly the blazed paths of life.

The history of medicine is the history of imagination—first superstition then concepts evolved from known facts, and finally experimental,

laboratory, and clinical verification of theory. Paré's ligature, Lister's antiseptics, Morton's and Long's anesthesia, are but three of the thousands of milestones that mark the path of imagination that great physicians have trod. Pasteur has said "Without theory practice is but routine born of habit. Theory alone is able to call into being and develop the spirit of invention."

The American College of Surgeons is interested not alone in assuring competent care to the sick but also in advancing the frontiers of medical knowledge. In our intense study of the obvious and practical we should not neglect to emphasize that unselfish service, personal and professional honesty, the urge to seek new truths, industry, broad culture, judgment and imagination, even more than technical efficiency, are the qualities that have given American surgeons an enviable position in international surgery. It is these that inspired McDowell when he did his first ovariectomy, Post when he first tied the femoral artery for popliteal aneurysm, and Beaumont when he investigated the function of the stomach on Alexis St. Martin. It is these that made Dudley Mott, Brashear, Jameson, Wyman, and Sims trail markers in the surgery of the new world. It is these that brought fame to our Senns, Fengers, Murphys, to our Bulls, Warrens, Agnews, that inspired our Mayos, Criles and Martins.

Technical dexterity in surgery is but the vehicle for the translation of these intangible qualities into surgical eminence. Elusive though they may be, they alone lead to enduring fame.

I paraphrase for you this sentence of Renan's: "Fame is a great coquette. She will not be sought too passionately, but often is most responsive to indifference. She escapes when she seems to be caught, she surrenders if patiently waited for, showing herself after farewells have been taken but inexorable when loved too ardently."

FUNDAMENTALS OF SPECIALISM¹

J BENTLEY SQUIER, M.D., F.A.C.S., New York

IN earliest recorded history the physician was priest, magician and medicine man. As human intelligence advanced to higher levels he was forced to split up his activities and declare himself. Some became priests, some charlatans, and others medical men.

In Egypt, sixteen centuries before the advent of Christ, this had already happened. But in other parts of the world where intellectual processes were slower in unfolding it did not occur until many centuries later. When Herodotus made his much exploited journey he found medical men even then further concentrating their endeavors for there was a special physician for almost every disease. The so called overspecialization of modern medicine might therefore be considered a reversion to type possessing at least, a precedent in antiquity.

The passing of the "old time" practitioner has been made a subject of much lamentation and from a purely sentimental angle deservedly for embodying as he often did, the attributes of friend, priest and physician, he held a very personal relation to his patient and his virtues have been loudly extolled. The paucity of his scientific information was offset by a great breadth of character and a wealth of human understanding. These qualities will ever remain the most distinguishing signs of greatness in any physician of whatever period. We pride ourselves upon the prodigious developments of theoretical and applied science which the past fifty years have produced, but in the minds of many exists a grave doubt as to how greatly all of these have added to the total of human happiness.

Every new step on the path of knowledge had opened to our vision uncharted deserts of human ignorance. If the goal of scientific progress is the production of human happiness, we of today may become objects of severe criticism fifty years hence for not having better utilized the scientific discoveries of this generation. It behooves us then to acquire the old time doctor's human understanding, kindly disposition and humble attitude for these are fundamentals of our calling, and also in order to neutralize any criticism of our own shortcomings which in years to come is bound to be made.

It is still within the ken of the older generation when a specialist in medicine was looked upon askance—as if possessing mental obliquity. But

the passing of years has effaced that view and now specialization within medicine has become as necessary as specialization in every other branch of science or profession. In engineering there are chemical, civil, electrical, and mechanical engineers. In law there are those who devote themselves to banking, civil, corporate or criminal law and so forth.

For as the world has aged, knowledge has increased to such an extent that it is now beyond human intelligence for any one individual to learn in the short span of life but a part of the existing information concerning any science or profession. To attain proficiency necessitates concentration upon a limited field and any improvement brought to this end will be beneficial to all. Every outstanding advance in medicine has resulted from intensified effort on one problem, the solution to which has opened the way to further progress.

It is to be regretted that the thought still exists in the minds of many that when a physician becomes a specialist he at once lays claim to superior proficiency. Whereas, by limiting his work he is but making a laudable effort to acquire proficiency.

The division of physicians into two main groups, one interested in medicine the other in surgery has given rise to much misunderstanding. This grouping has developed from a difference in indicated therapy and not from a difference in medical thought. In the final analysis, surgery is but a therapeutic measure for the treatment of certain diseases, injuries, or the correction of deformities and so on. An expenditure of more time and effort is required to learn how skillfully to administer surgical therapy than to administer a dose of medicine, but to be able to determine which type of therapy should be used requires similar fundamental knowledge.

The surgical remedy however, frequently necessitates adding injury to the tissues of the body by wound production, thereby injecting a second healing problem. The surgeon must heal the patient of the wound as well as the disease. During the course of this wound healing many complications may develop which require extensive medical knowledge in order to treat them intelligently. The patient may succumb to the disease or to complications arising directly or indirectly from the administration of the surgical

Henry Lunn

remedy. The surgeon then has to share with disease the responsibility of death while in the purely medical care of the sick if one remedy fails others are forthcoming or if all fail the demise of the patient becomes an act of fate. Not so in surgery, for the psychology of people is such that in their minds the thought lingers that if another remedy had been used or another surgeon had been in charge the result might have been different. The reverse of this however is stimulating for when surgical therapy is successful in effecting a cure it becomes more a testimony to the personal excellence of the surgeon than to the therapy instituted for his service has been definite individualistic and in no manner speculative.

He will be judged absolutely upon the outcome of his own act and he must be in a position to justify it at every angle. A surgeon therefore, should possess not only the technical skill properly to administer the surgical remedy but should be capable also of recognizing the possible presence of coexistent pathological lesions in any patient. He should be able to evaluate the influence for or against surgical interference which added lesions may produce. If the surgeon has to rely upon the judgment of others for this knowledge, he has not the proper conception of his responsibility.

This is but further endorsement of the time worn adage—To be a good surgeon one must first become a good physician. A good surgeon must combine the qualities of both. Changing times will never vary the wisdom of this advice, but in the hurry of every day life to become producers, many disregard it in an effort to make a short cut to economic success. The attention of such individuals should be directed to the facts elicited by a survey of the earning capacity of the profession compiled by the American Medical Association. It brought out that the largest gross incomes are made by physicians who have spent ten or more years in preparation and the low gross incomes are among the physicians who have had three years or less of preparation.

The road to the attainment of excellence in any branch of medicine or surgery is the same long route. The student in starting to follow this route soon finds it a maze. He becomes confused by the chaos existing in undergraduate medical education. This chaos has been produced by the tremendous mass of new information which the past fifty years have brought to all branches of science. Men have been intellectually unequipped to make proper use of it. In an attempt to keep abreast of the rapid strides of modern medicine,

the faculties of medical schools have added new requirements and subjects to the curriculum to such an extent that it is almost impossible for the student to acquire during his undergraduate course more than a smattering knowledge concerning many of them. The Commission on Medical Education of the Association of American Medical Colleges has been trying since 1925 to arrive at a sensible solution of this increasingly difficult problem. That they will succeed is certain but in the meanwhile the student on his way to licentiate in medicine plods wearily on.

The overcrowded curriculum may, however, be of use if it produces in the student a mind a realization of the vast amount of mental exertion necessary to acquire a working knowledge of the science of medicine. For he must understand that he is not learning a trade and if he is to become learned in his profession will have to continue to study until the last of his working days.

It is my belief that before deciding to take up any one specialty in medicine or surgery, a recent graduate should be required to spend two years as an interne in the medical service of a hospital. If, during this period he can find time to study psychology he will never regret the extra effort, for all through his future professional life it will enable him better to understand a patient's viewpoint. It will also help him more easily to establish mental contact with a patient and thus more quickly gain the patient's confidence.

The reason for insistence upon preliminary medical internship is based upon many factors. An individual can never be sure that he will be able to fit into the specialty of medicine of his ambition. He may be unable to earn a living at it and be forced to select another.

Only about 15 per cent of patients require the services of specialists and it is wise for every physician to have had a preliminary hospital internship which gives broad medical training in order to readily adjust himself to unforeseen circumstances.

Having finished his medical service he is then ready for surgical training. If he elects general surgery two more years should be spent in the general surgical wards followed by a surgical fellowship of at least one year before being allowed to practice surgery. If he elects a surgical specialty he should devote at least one year to study in the general surgical wards and then two years in the wards of the elected specialty. This makes five years spent in hospital training and it may appear a lengthy apprenticeship prior to commencing practice, but better than curtailment, would be to reduce the time spent in acquiring

the academic requirements for admission to the undergraduate medical school. A student of medicine should be allowed to commence the study at an earlier age, so that he may still be in the impressionable years when his first contact with patients takes place. Place responsibility upon his shoulders early for it sooner makes him able to meet it.

The medical professions are now separated into groups variously devoted to experimental, research preventive teaching, and clinical medicine, hospital administration, public health service sociology etc. Medical service is being considered from a much wider angle. Society is insisting upon a more effective organization of medical service for the people as a whole rather than as individuals. This being the case, readjustments in medical education are unavoidable. Progress has created new responsibilities which fall not upon governments but on those who are masters of scientific method, the physicians themselves, and must be shouldered by them, if the profession is to retain its autonomy and independence. This situation has been only partly recognized by the profession even though considerable energy is being expended toward making opportunities for extension or graduate training for those desiring to enter any special group. Graduate education is the question of the hour and universities, hospitals, county medical societies, and academies of medicine are endeavoring to create and meet demand for it.

The necessity for a continuing education is, of course not new to the Fellows of this organization because an appreciation of this necessity actuated its formation. However with the increasing opportunities for graduate training, a conviction has arisen, both within and without the profession, that some means should be taken to compel those who practice as specialists to have had adequate training to warrant them in making use of such an appellation. This was most forcibly stated in the biennial survey of education made by Willard C. Rappleye for the Department of the Interior of the United States Government in 1928 and 1930. One of the concluding paragraphs of his report on medical education was as follows:

"The training of specialists is another phase of the larger problems of training personnel to meet the medical needs of the country. The time will come when the medical profession and the public authorities will devise ways and means of guaranteeing to the public that those who claim to be specialists are, in fact, competent by training and experience to perform the service they claim to be able to render."

This conviction is not limited to our country but is world wide, and certain European nations have made definite progress toward legalization of specialists. Although bills have been introduced in some of our States with a view to legalization of specialists, I believe it will be a sad commentary on the profession if further licensing by the government becomes necessary. There exists within this College the potentialities for the solution of this problem.

Universities are appreciating that definite courses for advanced study in medicine and surgery should be offered—leading to acquisition of special knowledge sufficient to justify a physician taking such courses to enter the practice of a specialty. Columbia University grants recognition for acceptable work in the clinical specialties by means of a degree of Master of Science. This degree does not designate to which special field of study the student has devoted himself. The requirements for the degree are broad in order to permit of flexibility in training for the various specialties. The requirements for admission to study for the degree are evidence of graduation from an approved medical school and the completion of an internship of not less than one year after graduation. The course extends over three years in the University or in hospitals recognized by it, at least one year of which must be spent in the University. Intensive study in anatomy embryology physiology pathology bacteriology and in other fields of science is required as well as an active experience during the three year period of not less than eighteen months spent in the hospital, clinics, and diagnostic laboratories of the specialty elected. One university having initiated this others will join in supplying similar courses leading to a degree or otherwise.

The time is propitious and opportune for the American College of Surgeons to undertake another great work, which will become as far reaching in beneficial effect as that of standardization of hospitals. I would suggest, therefore, that from the already appointed committee on Graduate and Under-Graduate Teaching of Surgery and the Specialists the College Institute a forum for discussion of graduate medical educational problems. To this forum should be invited Fellows of the College who are teaching in institutions where graduate medicine is a part of the curriculum. Representation should also be requested from the Association of American Medical Colleges. By interchange of ideas, and using the University requirements leading to the degree of Master of Science as a basis for discussion, definite standards should be determined for

graduate training in every clinical surgical specialty. This training should be so comprehensive that there could be no shadow of doubt about a physician, who had been so trained, being able to qualify as a specialist in that branch of surgery in which he had majored. These standards of training having been formulated, ways should be devised to supply them, as well as means to have them made easily accessible to physicians in different localities. Supplying the courses of training should not present difficulties for on the roster of the Fellows of the American College of Surgeons are over ten thousand surgeons and surgical specialists and the teachers of surgery and its specialties in the Universities medical schools, and hospitals of the United States are with few exceptions Fellows of the College. Enlisting their aid and enthusiasm and by careful co-ordination similar courses technical and other experience could be made available in a multitude of centers. A merger of all approved agencies for graduate medical teaching to a labor of this kind, would effect a correlated educational program and would prevent the occurrence of chaos in graduate instruction which has been such a source of confusion in undergraduate training. The recent graduate from a medical school has a year or so of hospital internship but even then is without definite ideas as to how to fit himself for special practice.

The College having determined standards of training for special practice and having inspired making the acquisition of them accessible will be in a position properly to guide such an individual.

The College will become the supreme court for evaluating the excellence of the courses given in all centers of graduate training and its assump-

tion of this leadership will prove a most effective stimulus toward furthering graduate study in every branch of medicine or surgery.

There is one step further for the College to take—the most important step—and that step is making it imperative for every future member of the junior candidate group to acquire this fundamental training. For the sake of argument let us suppose that the requirements which the College has agreed upon are very comparable to the requirements for the degree of Master of Science. The junior candidate will have seven years before becoming eligible to Fellowship in which to acquire the knowledge and experience which by intensive study the Master of Science must acquire in three years. Many of the courses could be taken in different periods and in different institutions, and upon successful completion of any prescribed course a certificate would be given testifying to the fact by the institution in which the course was taken. When the candidate has received certificates of successful completion of all training requirements then upon submission of the one hundred acceptable case records at present demanded he is eligible for Fellowship.

For as in the ancient days the public forced the medical men to declare themselves as either priest, thaumaturge or medicine man so in the future will it become incumbent for physicians to declare which branch of medicine they are qualified by adequate training to practice with the added obligation of supplying a guarantee.

Let us make Fellowship in the American College of Surgeons the guarantee to the public that a physician possessing such Fellowship has received the proper fundamental training and experience to qualify as a specialist.

PRESENTATION OF HONORARY FELLOWS

FRANKLIN H. MARTIN M.D., F.A.C.S., CHICAGO

AT the Convocation on Friday evening Honorary Fellowships were conferred by the President on the following eminent surgeons

Sir George Lenthal Cheate London, England
Eminent Surgeon Knight Commander Order of the Bath
Commander Royal Victorian Order
Fellow Royal College of Surgeons, England
Walker Prize 1926-1931 Consulting Surgeon and Eminent Lecturer in Surgery Kings

College Hospital. Introduced by Dr. C. Gordon Heyd.

Professor José Goyanes C. Madrid, Spain
Distinguished Doctor of Medicine and Surgery
Author and Philosopher, Professor of Surgery to the General Hospital of Madrid Founder and President of the Society of Surgery of Madrid
Member of the National Academy of Medicine
Doctor Honoris Causa of the University of Bordeaux. Introduced by Dr. Rudolph Matas.

PRESENTATION OF CANDIDATES—CLASS OF 1932

FRANKLIN H. MARTIN M.D. F.A.C.S. CHICAGO

IN behalf of the Board of Regents of the American College of Surgeons, I have the honor to present for Fellowship in the College candidates as follows

United States	633
Canada	1
Alaska	1
Porto Rico	
Australia	1
Costa Rica	
Cuba	1
Korea	1
Peru	1
Republic of Panama	1
Total	633

There were 4,588 applications for Fellowship on file January 1, 1932. Seven hundred and seventeen of them were already approved by their State or Provincial Committees on Credentials. 1,786 were presented to State and Provincial Committees on Credentials during this year. Of these only 811 or 45.5 per cent, were approved and recommended for examination. Of the total recommended for Fellowship before and since January 1, 1932 (1,538) our careful sifting process has admitted to Fellowship only 633 or 41.3 per cent, constituting the candidates who are here present.

Surely if we pay tribute where tribute is due we must pay full portion to the magnificent group which is before us this evening. Veritably they are the survival of the fittest.

They are to be congratulated and the College is to be congratulated but above all we must congratulate the people who shall in the future seek their services.

Mr. President. Inasmuch as the candidates herewith presented have fulfilled all of the requirements for admission and have affirmed the Fellowship Pledge of the American College of Surgeons on authority of the Board of Regents of the College I take great pleasure in presenting them for Fellowship.

Each year as we receive a new class of candidates into Fellowship, I am impressed by the prestige of an institution that can influence such a goodly number of busy practitioners of surgery to seek its portals.

To the casual observer these men and women appear as one more group that is being enrolled into our ranks. Complacently this observer shrugs his shoulders and reflects "How easy!"

As an illustration let us enumerate the following facts

CASE HISTORY HONOR LIST AND PRIZE AWARD

ALLEN B KANAVEL MD F.A.C.S Chicago

MEDICINE has progressed through the careful study of clinical symptoms and imaginative experiment. Hippocrates as far as we know was the first to make comprehensive reports of his clinical studies. One may today diagnose the pathological lesions of the ancient Egyptians by study of the reports of physicians recorded in the papyri recovered from the tombs of the Pharaohs. Paré Potts Hunter Cooper Sydenham, and a host of others have engraved their names in the history of medicine through the careful analysis of symptoms and the adequate record of their clinical studies. **SURGERY GYNECOLOGY AND OBSTETRICS** was founded with the ideal of advancing the science of surgery by all practical means. The members of its Editorial Board are so heartily in sympathy with the program of the College and its demands that all patients should receive careful study as evidenced by adequate records that in 1930 they asked of the Board of Regents the privilege of presenting an annual prize in the form of a life Fellowship in the American College of Surgeons for the most acceptable set of case records presented by the candidates during the preceding year. The prize consists of five hundred dollars, invested in the name of the successful candidate for life dues in the American College of Surgeons and is accompanied by an appropriately engraved certificate of appreciation on behalf of the donor **SURGERY GYNECOLOGY AND OBSTETRICS**. The prize winner last year was Dr. H. H. Ogilvie, of San Antonio Texas.

In seeking the prize winner from among the successful candidates before you the committee has selected 45 sets of outstanding records. An analysis of the selected group discloses the fact

that they come from every part of the United States and one from Porto Rico. While New York, Boston, Chicago, New Orleans and St. Louis appear among the larger cities represented the greater proportion come from moderate sized or small cities throughout the country, thus demonstrating the widespread interest of the members of the College in careful case studies and records. From this group of 45 sets have been selected as being outstanding and the authors of these records have been placed upon an honor list. May I ask each honor man to rise as his name is read?

Charles B. Puestow, Chicago, Illinois
Reginald M. Norris, Jacksonville, Illinois
Leo M. Davidoff, New York, New York
William W. McGregor, Detroit, Michigan
Clyde H. Frederickson, Great Falls, Montana

And now, may I announce the prize winner from among this group and invite him to the platform to receive the certificate of appreciation from our official journal, and the formal receipt for life dues in the American College of Surgeons.

Will Dr. Frederickson please come to the platform?

Dr. Frederickson, this recognition of your work is an expression by the College of its belief that scientific investigation, careful records, and critical analysis of case histories elevates the standard of surgery and insures to patients the most efficient care. It is our hope that this expression of commendation may serve to stimulate others to emulate your example, advance the frontiers of surgical knowledge, and benefit those entrusted to our care. I congratulate you.

Each year as we receive a new class of candidates into Fellowship I am impressed by the prestige of an institution that can influence such a goodly number of busy practitioners of surgery to seek its portals.

To the casual observer these men and women appear as one more group that is being enrolled into our ranks. Complacently this observer shrugs his shoulders and reflects "How easy!"

As an illustration let us enumerate the following facts

There were 4,388 applications for Fellowship on file January 1, 1932. Seven hundred and seventeen of them were already approved by their State or Provincial Committees on Credentials. 1,786 were presented to State and Provincial Committees on Credentials during this year. Of these only 811 or 45.3 per cent, were approved and recommended for examination. Of the total recommended for Fellowship before and since January 1, 1932 (2,528) our careful sifting process has admitted to Fellowship only 633 or 41.3 per cent, constituting the candidates who are here present.

Surely if we pay tribute where tribute is due we must pay full portion to the magnificent group which is before us this evening. Veritably they are the survival of the fittest.

They are to be congratulated and the College is to be congratulated but above all, we must congratulate the people who shall in the future seek their services.

Mr. President Inasmuch as the candidates herewith presented have fulfilled all of the requirements for admission and have affirmed the Fellowship Pledge of the American College of Surgeons, on authority of the Board of Regents of the College, I take great pleasure in presenting them for Fellowship.

meetings, Dr. Franklin Martin became so impressed by the type of clinical teaching which was being given that it awakened in him a desire to place such teaching before all American surgeons. It was the right of a chance for the many to have opportunity comparable to that of the favored few. His creation of The Clinical Congress of Surgeons of North America was the first step toward the consummation of this desire. This society had its first meeting in 1910 and received the support of many noted surgeons and teachers of surgery.

However, after the second meeting, Dr. Martin realized that the scope of this society was much too limited to encompass his more ambitious plans for improving American surgery. Such, doubtless, was his frame of mind when on a November day in 1912 he boarded the 20th Century train at Chicago. He was on his way to direct the third meeting of the Congress to be held in New York. As the train rushed on with the passing of each milestone, new ideas presented themselves and his ambitious plans assumed concrete form.

Calling the train stenographer, he then and there dictated the ideals, the goals of ambition, and the plan or organization for a society more comprehensive in its aims—The American College of Surgeons. When the train pulled into New York, to him the College was already a living thing.

Abraham Lincoln while on a train to Gettysburg to honor its hallowed ground wrote a short appeal for renewed consecration of the people's lives to the cause of freedom. His inspired words ever remain a clarion call for devotion to democracy.

Franklin Martin while on a train, in five short paragraphs had written a clarion call to American surgeons to consecrate their lives for devotion to surgical idealism.

On the last day of the Congress, November 15, 1912, Dr. Martin presented his resolutions for the foundation of the American College of Surgeons to over two thousand men who were attending the Clinical Congress. These resolutions read—there was silence—the audience pondered—could so small a group of surgeons influence and enlist a sufficient number of other surgeons to carry to successful conclusion such an ambitious undertaking?

Dr. John B. Murphy seconded Dr. Martin's plan, and then Dr. Edward Martin of Philadelphia, the president of the Congress, made one of his eloquent incisive appeals for the establishment of the College but warned against any action which might give the impression to others

that the contemplated project was of vain glorious conception.

The resolution was passed by overwhelming endorsement.

A Committee of Organization of twelve was appointed and the names of those men insured success for the College from its very beginning. Their lives had been devoted to furthering surgical idealism and their integrity of character had won the full confidence of the profession as well as of the laity.

Those appointed to the Committee of Organization were:

Edward Martin	Emmett Rixford
John B. Murphy	Rudolph Matas
Albert J. Ochsner	Charles H. Mayo
Frederick J. Cotton	George F. Emerson
	Brewer
John M. T. Finney	Walter W. Chipman
George W. Crile	and Franklin H. Martin

These names should be graven deep in the hearts of all Fellows of the College as they are graven deep in the hearts of those who have been so fortunate as to enjoy their friendships.

This committee in its work of organization was not hampered by tradition. Tradition was in the making. Ten days following ratification of the proposal for the establishment of the College, the Secretary of the State of Illinois on November 25, 1912, certified that the College was a legally organized corporation under the laws of that state. The first Convocation took place on the evening of November 13, 1913 at the Congress Hotel in Chicago. Dr. John M. T. Finney was elected the first president of the College.

It was an encouraging incident at this first meeting to receive greeting and wishes for success from the Royal College of Surgeons of England. These were extended by its president, Sir Rickman J. Godlee.

Honorary Fellowship in our College having been conferred upon him, he then delivered the Fellowship address. In relating the motives which actuated the formation of the Royal College of Surgeons, Sir Rickman stressed that it was an attempt by British surgeons of over one hundred years ago finally to rid themselves of any remaining taint of the Barber's Guild of the Dark Ages or of the Company of Barber-Surgeons of the sixteenth and seventeenth centuries.

The academic atmosphere of the Royal College was of later development, and eventually it became the determining body for licensing British surgeons. The precise motives which initiated the formation of the Royal College of Surgeons

were quite dissimilar to those of the American College but the great desire to improve surgery was the ambition of both.

Nineteen years have passed since that first convocation. They have been years full of effort and mounting activities until now it is difficult to decide which have been most productive of result. The results obtained by the Committee on Hospital Standardization will perhaps always rank among its great achievements. The circumstance which brought about the formation of this committee and the decision to make a survey of the hospitals of the country are full of interest and I will devote a few remarks to their consideration.

The Founders of the College had not been subjected to examination as to their surgical capacity but by the time of the second convocation over two thousand applications for Fellowship had been received and the Regents appreciated that examination for admission to Fellowship must be instituted.

It was obvious that before admission, each applicant for Fellowship should possess an adequate background of surgical experience. Equally important however was for him to have strength of character to withstand absolutely every temptation to commercialize his calling. It was decided that a fair estimate of an applicant's surgical experience could be made by a careful examination of submitted case records of his personal work.

The estimation of his character must be left to his intimate associates, and for this the College would have to rely upon the judgment of his local confrères. A Central Committee on Credentials was appointed to pass upon the excellence of submitted records, with a local committee to pass upon the character and general fitness of any applicant. The examination of the submitted records, in many instances revealed a woeful lack of understanding of what really constituted a good case record, and many candidates reported that in the hospitals with which they were connected, no case records were even kept.

If this was the situation in many hospitals, what also were their surgical standards, what measures were being taken toward proper education of their internes, and divers other questions must be answered. To obtain this information an intimate survey of the hospitals of the country became imperative.

The Regents, however believed that such an investigation should be undertaken by the American Medical Association as it represented the medical profession as a whole.

Since 1910, the American Medical Association had been interested in classifying medical schools

and analyzing the results of examination of their graduates before state medical boards, and possibly on this account, were not interested in taking up another investigation at this time. Nevertheless the College determined to undertake the survey even though such an investigation presented many obstacles.

By what measures could the lay and medical boards of the hospitals of the country be induced to permit their institutions being investigated, classified, and standardized by the American College of Surgeons?

What presumption of a very young organization to consider that it was qualified to pass judgment on the efficiency of institutions possessing traditions of excellence which many of them held! To combat this opposition, the hospital authorities were informed that the contemplated investigations were instigated by a desire on the part of the College to be of valuable service to them to demonstrate how to make their hospitals of better service to the patients, to the community and a more advantageous workshop for their professional staff. To outline the standard of service they should demand of their medical staff, how to evaluate such service and the standard of ethics their staff should possess.

As this work progressed, those in charge were continually being consulted by heads of hospitals from all over the world as to how to increase the efficiency of their institutions.

Today there is scarcely a hospital in our country whose personnel fails to be filled with pride to have their institution included in the ranking group of those which have been investigated. The initiation of this work required all the tact, patience and perseverance that the College could muster. The carrying on of the work to a successful issue took years of painstaking labor on the part of the officers of the College and those associated with them in this special undertaking.

If the American College of Surgeons in the twenty years since its incorporation had accomplished nothing else than the improvement which it has produced in raising the standard of American hospitals this work alone would have more than justified its birth.

Standardization of hospitals was commenced during the period when Dr. John G. Bowman was one of its officers. It was at this time that the Regents drafted the first tentative outline of the minimum standard for hospitals. Our Director General in commenting upon this outline in his report delivered at the annual meeting in 1924 said "This document has now achieved international fame and has become to hospital better

ment what the Sermon on the Mount is to a great religion.

Dr. Bowman had exerted a unique influence on the College, for having had a scholastic and not a medical training, he viewed our problems in a more detached manner than could a man of medical mind. An idealist himself he appreciated idealism in others and was able to expound the doctrine of surgical idealism with inspiring conviction. Dr. Bowman was called to become Chancellor of the University of Pittsburgh.

The standardization of hospitals was a project which required considerable expenditure of money, the raising of the endowment fund to meet this and the other increasing expenses of the College was a most creditable accomplishment in these early years. The Fellows at once responded to the call for funds, and by the time of the third convocation the sum of over two hundred and fifty thousand dollars had been pledged.

The fund has grown year by year until now it is well over one million dollars. It has been well invested and the income derived from it judiciously expended. The financial sagacity of those Fellows who have guarded this and all other funds of the College deserves commendation. An examination of the securities held by the College at this period of financial deflation produces admiration for the judgment of these men.

This spirit of the Fellows to give of their own without waiting for aid from philanthropical sources was the strongest demonstration of their belief in this institution. A similar spirit was exhibited, when it became expedient to determine which city—in the United States—should be chosen as the permanent home for the College. There was much discussion and the pros and cons make a long story. Finally it was decided as such questions usually are by the financial equation.

The Fellows of the College residing in Chicago and their friends raised the money, purchased a site in Chicago, and gave it to the College. A few years later Chicago again made the College its debtor by presenting a building a monument to one of America's greatest surgeons, Dr. John B. Murphy. There is a peculiarly significant sentiment in the principal College building being a memorial to him for you will recall that it was Dr. Murphy who seconded Dr. Martin's resolution for the foundation of the American College of Surgeons. It was to him Dr. Martin had first confided his ambitious project, and it was from him that Dr. Martin had received the most sympathetic encouragement.

Next year the College will meet in Chicago, and you Fellows will have opportunity to view its

home. If you start from Wabash Avenue and walk East on the north side of Erie street, you will pass first, the Administration Building of the College (a gift from Chicago Fellows), then the Murphy Memorial Hall (a gift from the family and admirers of Dr. Murphy) and last, what is to be the greatest gift of all—54 East Erie Street and its contents—the Journal of SURGERY, GYNECOLOGY AND OBSTETRICS (to be a gift from Dr. and Mrs. Franklin H. Martin). Pause a moment on the corner of Rush Street and consider how greatly the Journal has aided the College. Before the College was ever contemplated, this Journal was already a publication of international importance. Later carrying our propaganda it helped us to win respect of the surgical world for the ideals of the American College of Surgeons.

The Journal will become the most determining gift for success. The north side of Erie Street represents fulfillment. With this thought in mind cross to the south side and walk back. The first half of the block was bought by the College in 1928—and imagination visualizes a future building to house the library and museum; the second half of the block is now under consideration for developments in the future. The south side of Erie Street represents hopes deferred but long before another twenty years have elapsed these too will be fulfilled.

In 1916 the College activities became subservient to medical preparedness as war clouds were gathering and all efforts were extended to be in readiness if war was declared. The Secretary General of the College was appointed by our government to be the chairman of the Medical Board of the Council of National Defense. This appointment brought grave responsibilities to him and the manner in which he met them will ever be a source of great pride to this organization.

The Fellows responded nobly to the call for enlistment in the Reserve Corps of the Army and Navy. Dr. Crile who was then president of the College had his Lakeside Hospital Unit mobilized in Philadelphia where the College met that year. It was an object lesson. When war was declared over 90 per cent of the Fellows were in uniform and those not in uniform were in some governmental service. However, what was true of the Fellows of the College was equally true of the whole medical profession of the United States. Never in history has the medical profession ever failed to respond to the call of duty. The World War brought our surgeons and medical men in close contact with those of our Allies. Working shoulder to shoulder with them under tragic circumstances produced mutual respect and regard.

Two episodes in the history of the College may bear retelling, even though many of you may be familiar with them.

The year following Sir Rickman Godlee's visit to the first Convocation the College received a gift of a gavel from him and upon it was inscribed "This mallet was devised and used by Lord Lister and is presented to the American College of Surgeons by Sir Rickman J. Godlee then president Royal College of Surgeons England, in memory of his visit to Chicago November 1913."

This, indeed was a gracious gesture. Lord Lister was an uncle of Sir Rickman and with this gift a priceless family heirloom came into the possession of the College.

The second episode occurred after the war when the surgeons of the British armies presented the Great Mace with the following inscription: "From the Consulting Surgeons of the British Armies to the American College of Surgeons, in memory of mutual work and good fellowship in the Great War 1914-1918."

The war over the activities of the College grew apace. The acquiring of the College library and the establishment of a Department of Literary Research and the service which that department has rendered to the Fellows of the College is an engrossing tale.

In an attempt to extend clinical teaching, the College in 1919 arranged for sectional meetings so that smaller groups of the Fellows could discuss questions and receive instructions from well known leaders in surgery.

These sectional meetings included one evening set apart when the laity were invited to attend. They would be addressed by local professional men and officers of the College. The subjects presented were medical ones of popular interest. The lay public were to be admitted to professional confidence. Opposition to this innovation by more conservative Fellows was acute however as it has ever been the policy of the College properly to instruct the public in medical matters, the innovation succeeded. Today these sectional meetings are among the most favored of the College activities. We have taken the public into our confidence and by so doing have gained theirs. This we must never lose. The belief of the College that the public should be kept informed concerning medical advances is only a reflection of the present world point of view. Medicine has long since ceased to be a mystery in the minds of educated people. It is our duty to them to help make medical truths understandable, to keep them from being duped by false statements of impossi-

ble cures and in every way indicate that the College was formed for their interest as well as for the profession.

The Department of Clinical Research has expanded its work until now it requires two Boards and five Committees to take care of it.

The Board on Industrial Medicine and Traumatic Surgery has already accomplished much. Industrial medicine is passing through deep waters with the problem of compensation practice.

If this Board can exert its influence toward a solution the College will have performed another great public service. Compensation practice is inherently different from regular practice. The relation of the physician to the patient is not a natural one. I shall not go into the many disagreeable features. Compensation practice in many localities has fallen into such bad favor that many physicians do not, as a general rule desire to undertake it, thus producing a tendency for concentration into the hands of the unscrupulous. One way in which the situation might be corrected would be to take this type of practice out of the hands of individuals and place it in the clinics of the reputable hospitals of the country. I am aware, that there are objections to this but the point requiring most emphasis, in advocating the establishment of industrial clinics in our reputable hospitals is that such a step could in no wise be interpreted as furthering State medicine. Those clinics would have to be especially organized to handle industrial accidents. Their expenses would be paid for by insurance companies. Being paid clinics they would provide part time positions for a great number of young surgeons. In this way compensation practice would be widely distributed among young medical men of high caliber. In addition, these clinics would provide a tremendous amount of material for statistical and research purposes. Comparative methods of treatment could be followed intelligently and results statistically analyzed so that much might be learned as to how to obtain the best results at the lowest cost in the shortest possible time. This is a particularly good moment to interest hospitals in this project. Many are financially embarrassed, and industrial clinics would be a sure source of considerable revenue. I have talked at some length about this subject because in many of the larger cities the abuses have approached a racketeering stage.

I would thus permitted acquaint you men who tonight are being admitted to Fellowship with all the interests which the College has undertaken, but the few I have mentioned may give you some idea of the scope of its many activities.

I would, time permitted, pay personal tribute to each one of the officers and regents, who in the years gone by have sacrificed their time and given of themselves to further the interest of the College.

Often while reflecting on the College, the thought has come to me, that with Finney of Baltimore, Crile of Cleveland, the Mayos of Rochester, Armstrong and Chipman of Montreal, Martin and Deaver of Philadelphia, Cushing of Boston, Ochsner and Kanavel of Chicago, Matas and Miller of New Orleans, Brewer and Stewart of New York, and Ireland of Washington to help him, maybe Dr. Martin did not have so difficult a task in directing the College to its present enviable position.

It has been nevertheless an unselfish service on the part of each and when his term of office expired has continued working even more assiduously for the good of the College. When I say good of the College it presupposes good for humanity and good for each Fellow of the College.

During its short life the scientific contributions of many of the Fellows of the American College of

Surgeons have helped to bring world recognition to American surgery.

It has been a wonderful experience to have lived and worked during this Renaissance of Surgery, but scientific advance is an endless adventure. It is not for us to be satisfied with what has been accomplished but to look beyond.

The College with many of its ambitions already realized has as yet but indented the surface of opportunity.

This child of Franklin Martin's imagination and foresight will be of age in another year. The child has had many watching its growth and many guiding its youthful steps and you, new Fellows, will have to assume the guardianship of its advancing years. You bring new faces, new ideas, and new energy to us, and to you—we give our faith.

Remember always, that the American College of Surgeons has never an axe to grind save one and that must ever be kept, ground to a Toledo edge to blaze the trail through the dark wilderness of sophistry into the sunlight of scientific truth.

NEW VIEWPOINTS IN PHYSICS¹

ROBERT A. MILLIKAN Ph.D. PASADENA, CALIFORNIA

THE past twenty years have been the most surprising and the most extraordinary in the history of science in bringing to light new phenomena completely unpredictable from the simple rigidly mechanical conceptions of the nineteenth century and they have taught the physicist a lesson of modesty open mindedness and reluctance to extend his generalizations beyond the range of his experimental verifications, such as he has not had in the past and such as some other branches of knowledge still lack. It is, therefore, useful for the other sciences and for the public to follow as well as they can the new experimental findings in physics so that they may avoid better than they now do and better than the physicist has done in the past *dogmatic assertiveness without knowledge* whether it be in science philosophy sociology politics, or theology. I am therefore, passing in rapid review tonight first the growth of our ideas about the atomic nature of matter which led to the general acceptance within our century of the kinetic and atomic theories in all branches of what we called the physics of matter.

I am then passing in review the growth of our ideas from 1800 A.D. down in that other half of physics which we call the physics of the ether until by the beginning of this century the wave theory of radiation of all sorts, from wireless waves to cosmic waves, became generally accepted. Everything worked well so long as these two fields were kept separate, but within the past two decades they have revolted completely against such separation. We have gone over into new fields of experimental studies, in which we deal not with large scale phenomena but with isolated elementary processes themselves, and in

these elementary processes, in which, for example one single electron is acted upon by light waves, or X rays, or gamma rays, we have found that either waves—which represent in our analysis continuous processes—act not like waves but like particles. Also within the past 5 years, we have found experimentally that streams of particles, whether they be electrons or atoms, exhibit all the wave properties which we have heretofore attributed only to radiation phenomena. In other words, the physicist has been obliged to find some way to reconcile apparently contradictory behaviors. Personally I see no way out of the dilemma except to assume that, at bottom, the world of physical experimentation consists of particles, and to try to get wave properties, whether of atoms, electrons, or photons, out of statistical behavior of great swarms of these different sorts of particles.

Efforts are now being made with some success, by theoretical physicists to derive such wave properties out of the statistical behavior of particles, though other theorists prefer to reverse the process and to consider the wave properties as the more fundamental. At any rate, the wholly unexpected discovery that experimentally at least all interference phenomena can be obtained from streams of flying particles represents one of the most amazing developments in the whole history of science and should teach physicists and all mankind the lesson of the danger of extending our generalizations beyond the range of experimental verification. Modern physics has been taught by its mistakes to agree with the poet Shakespeare that there are more things in Heaven and earth than have been dreamed of in our philosophies.

Abstract of Fellowship Address, presented before the Convocation of the American College of Surgeons, St. Louis, Missouri, October 1, 1931.

Robert A. Mullen

OPHTHALMOLOGY, OTOLARYNGOLOGY

SECTION ON OPHTHALMOLOGY

THIS section met in the ballroom of the Statler Hotel on the evening of Tuesday, October 18, with Carl Barck, M.D., St. Louis, presiding. Two papers, abstracts of which follow, were presented and will be published elsewhere.

HIGHWAYS AND BYWAYS IN OPHTHALMOLOGY

HANA BARKAN, M.D., San Francisco. There are a number of interesting literary, artistic and mythological fields of knowledge into which one can dip and find the eye of interest, with often a deep speculative value in arousing one's mental processes. The eye in art has been handled differently by different painters of different centuries; the eye in statues has been represented as a blank or as composed of jewels; the eye in mythology has been given certain values, as for instance the ox-eyed Juno or gray-eyed Athene. Descriptions of the eyes of famous men are found in Plutarch's *Lives*. The eye diseases of famous men such as Goethe, Wagner, Carlyle, Milton, Lincoln and others have been fully described by our American author Gould, and inferences have been drawn as to their relationship to the general individual and his work. The superstitions concerning the eye are many: the evil eye—the origin of the pennies on a dead man's eyes and the representation of a witch with cross eyes. The whole field of ophthalmology contains no more interesting subject of literary research than mention of the eye as an organ expressing love, hate, despair, tragedy, cunning and other emotions as often represented in Shakespeare and the Bible. In gen-

eral the object of this paper has been to indicate many interesting allusions to the eye in literature, art and superstition.

CHANGES IN OCULAR REFRACTION

EDWARD JACKSON, M.D., Denver, Colorado. Development of the refractive media of the eye is well started in the first month of fetal life, and the lens continues to grow until old age. Changes in refraction occur at any age and are most common in childhood and after middle life. At birth almost all eyes show hyperopia, which diminishes with the normal growth of the eyeball. Myopia appears during school life and may increase unless controlled by correcting glasses. Astigmatism may change at any age and does in almost all eyes in later life from changes in the crystalline lens, whether these cause cataract or not.

Uncorrected errors of refraction are the most common and serious handicap for the higher occupations and popular amusements of civilized life. They are recognized by the symptoms they cause, which can only be understood and met by those who have the full medical education. The decrease of accommodation after middle life, makes slight changes of focus more important and annoying, and changes of astigmatism are very often overlooked. The time of life when testing for glasses is often left to the optician, is the time that the most careful and exact measurement of the focus of the eye is of special importance, and when it gives important information about the existence of degenerative changes in the eye or other parts of the body.

SECTION ON OTOLARYNGOLOGY

AT the meeting of this section in the ballroom of the Statler Hotel on the evening of Thursday, October 20, Max A. Goldstein, M.D., St. Louis, presided. The following papers were presented: *History and Development of the Operative Treatment of Facial Palsy*, by Arthur B.

Duel, M.D., New York. This paper is published with illustrations in this issue. A second paper on *Suppuration of the Petrous Apex in Relation to Meningitis* was read by Wells P. Eagleton, M.D., Newark, New Jersey, and is to be published elsewhere.

SYMPOSIUM CANCER IS CURABLE

THE CURABILITY OF CANCER

FRANKLIN H. MARTIN M.D. F.A.C.S., CHICAGO

MAY I cite briefly the objectives that were in my mind when this symposium on the Curability of Cancer was organized. Through the reports of cancer cures that will follow it is my hope

1. To impress upon the practitioners of scientific medicine, and indirectly upon the public the fact that carcinoma is curable by the use of well known and established methods of treatment.

2. To point out in a convincing manner that if all cases of cancer could be diagnosed early and treated promptly in their incipency the annual death rate from the disease, now recorded as 150,000 in the United States and Canada would be reduced by at least 33 per cent, or 50,000 per year. Even if only one-half of the cancer cases could be diagnosed early and properly treated, the death rate would be reduced by 25,000 per year.

3. To bring together the group of distinguished clinicians here present—an overwhelming authority—to present definite statements of the impressive number of cases of cancer that have actually been cured. This preponderance of evidence, so convincing as an object lesson, will impel ever increasing numbers of the people to demand facilities, through scientific doctors, for annual or semi-annual examinations, so that not only cancer, but any and all diseases may be discovered in their incipency when they are amenable to treatment.

4. To get the maximum of ethical publicity of the reports. This will furnish convincing evidence to our hospitals, our local medical societies, and our already established clinics, and encourage them to furnish facilities whereby every physician who is practicing scientific medicine will have available the necessary equipment and trained aids to insure the comprehensive examination of his patients.

5. To convince the profession and the public that even though cancer is already apparently in a later stage of its development, if it is subjected to proper treatment, its progress may often be stayed, and the disease not infrequently cured to

make these facts so obvious that a general policy will be established to treat systematically every case of cancer in whatever stage of advance not only because of the immediate or remote possibility of a cure but because palliative measures would bring great encouragement and relief of distressing symptoms.

6. To establish a universal policy among physicians and surgeons of reporting cancer cures rather than to present the involved comparative statistics that dwell particularly on the cases not cured.

If we here present accomplish the full humanitarian purposes for which this symposium was organized, the discouraging psychosis that now exists in the minds of the profession as well as the public will be dispelled. A consciousness that cancer is curable will be established in the minds of all fear will be displaced by a spirit of hopefulness and every victim of cancer or suspected cancer will present himself for early diagnosis and treatment.

CANCER CURES—5 YEARS AND MORE

Reported by speakers in this symposium	4,335
Cases registered by American College of Surgeons	1,265
Cases reported in the literature, incomplete recent survey	3,050
Specially reported in this symposium	140
Total	8,890

CLASSIFICATION

Cervix	1,561
Fundus	345
Ovary	42
Breast	3,654
Bladder	233
Prostate	43
Kidney	125

Skin	266
Colon and Rectum	116
Bone	20
Other classifications	299
Total cancer cures 5 years and over	8,890

CANCER RELIEF

WALTER C. ALVAREZ, M.D., ROCHESTER MINNESOTA

I HOPE you will be patient with me as I do what I can to pinch hit for a great man. I am keenly interested in this program today because I feel the need for it. In spite of the great efforts that have been made to bring patients with carcinoma to the surgeon or the radio-therapist as early as possible, thousands of these people are still waiting months or years before they present themselves. There are several causes for this dilatoriness and some are beyond our control but one at least we must strive harder to remove and this is the hopeless, apathetic, or uninterested attitude of some of the physicians who first see the patients. Some of these doctors seem actually to be doubtful if cancer is ever cured.

So many of you are going to tell us of the splendid results that can be obtained in many cases of cancer that I am not going to say a word about this phase of the subject. The only point I would like to make is that more effort must be made to reach the general practitioner with brief summaries of what can be done in the way of curing cancer in the several parts of the body. For instance we must admit that cancer of the esophagus is hopeless hint, when taken early, cancer of the breast or colon or cervix is anything but hopeless. In the past, too much of this information has been published in special journals which are never seen by the general practitioner.

The physician must be taught, also, that even when, in a given case the disease looks incurable there is always a gambler's chance that with removal of the main growth health will return and metastatic growth will lie dormant for several years. A 5 year cure is wonderful but so also is a 2 year or a 3 year cure.

Finally, the profession must be encouraged to take better care of the forgotten man—the patient with inoperable carcinoma. Most of us physicians hate to see these poor people. We feel uncomfortable when talking to a man who has just been condemned to death—we hate to see the suffering in the faces of his relatives—we don't know what to do with him and as a result too often we say as little as possible—we urge him to go home, and we abandon him to the rapaciousness of the quack who lies waiting for him around the corner.

This is not right—we must not shirk our responsibilities in this way, and besides, in most cases there is much that we can do to add to the comfort of these patients. Often it pays to remove or

clean up the main growth. We may perhaps short-circuit an obstructing tumor in stomach or colon and thus give many months of good health. We can often clean up foul discharges and some times we can stop fiendish pain with a dose of roentgen rays. Occasionally to our astonishment, irradiation will even work a cure when none was expected.

We can do much to keep up the morale of the patient and his family, it is terrible to have to sit by idly and watch a loved one die and the kindest thing we can do for many of these families is to keep them busy doing something if we don't they are almost certain to fall into the hands of quacks and scoundrels.

Too often we do not even make a fight to see that the patient has enough morphine to relieve his pain and we do not always see to it that he has harmless sedatives so that he can sleep at night. (We now have the new drug Dilaudid which can be taken by mouth—it relieves pain much as morphine does, and it probably is not habit forming.)

In some cases we can raise the patient's resistance to the growth of the carcinoma with the help of a richer diet, injections of foreign protein, and transfusions of blood. There is no question that some persons have an enormous hereditary resistance to the development of cancer, and this resistance should be conserved.

In some cases it is worth while to try injections of lead, and I am hopeful that something will come of the experiments in which the whole body is being irradiated over a period of time. I would be willing to let a patient try anything that is not definitely injurious.

Unfortunately many physicians will hesitate to treat incurable cancer with any degree of hope and optimism for fear of being criticized by their colleagues. They will fear the accusation that they are treating the patient merely for the money that is to be made. This fear of blame would be largely removed if a great medical organization like this College were to approve officially of and advocate more palliative treatment.

It is reported in an ancient manuscript that Christ once on the Sabbath day saw a man working hard to shore up the foundations of a poor widow's house being undermined by a swollen stream. He said to him, Man if thou knowest what thou art doing blessed art thou, but if thou

TABLE I.—SUMMARY OF SALIENT RESULTS OF TREATMENT OF CARCINOMA AT THE MAYO CLINIC*

Organ involved		Percentage of patients living†	
		2 years later	3 years or more later
Stomach	795 patients traced following resection		34
Colon and rectum	603 patients traced following resection	47	33
Freedom of scarus	Lesions suitable for excision alone Lesions suitable for excision and irradiation Inoperable lesions treated by irradiation	27 46	23 21 13
Cervix of uterus	1266 patients traced Operable Borderline Inoperable Masked by previous treatment		27 62 7 75
Breast	179 patients operated on Without lymphatic involvement With lymphatic involvement	56 4	67 58
Kidney	57 patients operated on; some irradiated also		43
Bladder	506 patients treated by surgery and irradiation		28
Prostate gland	400 patients traced 264 cases of prostatectomy		12
Esophagus	226 patients traced, all died		
Thyroid gland	364 patients operated on 87 patients traced following operation and irradiation 77 patients traced after irradiation alone	33	27 54
Face	29 cases Without involvement of cartilage or bone With involvement of cartilage or bone		95 74
Eye	11 cases		43
Ovary	24 patients treated	47	39
Antrum of Stomach	27 patients with tumor primary in antrum 70 patients with tumor primary in stomach		29 18
Mouth	Surgical removal early Irradiation alone		16 13
Uterus and base of vagina	89 patients traced	16	
Larynx	84 patients traced Carcinoma graded 1 Carcinoma graded 2 Carcinoma graded 3, all died	27 97	
Lung	47 patients treated by irradiation; life prolonged		
Gall bladder	20 cases studied		3
Appendix	27 patients traced, no deaths from carcinoma		

*It must be remembered that the figures given here represent results obtained only in cases in which the disease could be attacked with a small probability of success.
†All patients traced.

knowest not what thou art doing cursed art thou! If we physicians can bring ourselves to help these poor patients because of our pity for them and our feelings of consecration to our work, I am sure we will be blessed.

In some cases of course the wise and kindly physician will advise against costly treatments if he thinks that they are quite hopeless and if the

patient is so poor that he must try to leave every thing possible to his wife and children.

Let us then go forward with a clearer knowledge of the type of case in which we most certainly can cure cancer as well as with a greater feeling of responsibility toward the many poor sufferers whom we now turn away with barely a word of advice.

IS CANCER CURABLE?

J M WAINWRIGHT M D F A C S SCRANTON PENNSYLVANIA

IT is the experience of everyone whose lot has led them to special interest in cancer surgery frequently to be asked "Do you ever cure a cancer?" Many times the question comes from those who should know better.

Other papers in this group will deal with results in large series of cases. This paper will not consider statistics or percentage results but will relate in brief a few cases which give somewhat striking proof that we do cure cancer.

THE BREAST

1 Miss C G was operated on at the age of 61 on October 13 1903. Her tumor had been noticed 6 years before. It was large. The microscopic examination was unquestionable and it showed infiltration of pectoralis major muscle fibers. This was the writer's second breast operation and it was not one to be proud of. This old lady was carefully followed. She remained well and active. The photograph shows her in August, 1923, at the age of 85 still in the active direction of her farm. In January 1930 she was found dead in bed at the age of 87 26 years and 3 months after operation. She had been examined a few months before and found apparently cancer free and with no special complaints (Fig. 1).

2 A doctor's mother aged 49, was operated on on January 30, 1910. She had had her tumor for 1 year. The microscopic examination was unquestionable and the axillary glands were involved. This lady at this writing is in good health, aged 71 and cancer free 22 years and 9 months later.

3. Another patient is well and cancer free at the age of 66 years 20 years after operation.

MELANOMATA WITH METASTASES

(than which few things are more malignant)

1 S. S. Operated on August 25 1905 aged 36. Four months before he had noticed a black tumor over the right scapula. Two months later he noticed a mass in the axilla. Within the next few months metastatic tumors were removed from the left shoulder and the opposite axilla. He had four operations in all the last January 6 1906. Microscopic examination unquestionable. This man is under close observation and is well and cancer free at this writing 27 years and 2 months after the first operation.

2 H. L., was operated on on January 7 1915. He had a rough pigmented mole on the right arm which a few months before metastasized to the glands in the neck. The mole and the glands were removed. The microscopic examination was unquestionable. This man is under close observation. Last examined July 1932, at which time he was well cancer free, and working regularly in the coal mines 17 years and 6 months after operation.

3 Mrs. A. C. operated on on August 23, 1912 aged 62. She had a melanotic patch under the right thumb nail. Six months previously it metastasized to the right axilla. Amputation of the thumb and removal of a mass the size of a baseball from the axilla. This patient kept under close

observation and remained cancer free and did hard farm work in the fields. She died suddenly of apoplexy aged 77 15 years after operation.

THE LIP

1 E. If. operated on on April 21 1904 aged 45 years for cancer of the lip. Section was unquestionable. Twice within the next few months the involved glands were removed from the neck. She was kept under close observation and remained well and cancer free. She was killed in an accident 23 years and 6 months after operation aged 68.

THE UTERUS

1 Mrs. M. B. aged 20 years. Treated by radium July 1 1920. She was in a very distressing stage of emaciation and cachexia. The entire vaginal vault was filled with a large cauliflower like mass and a mass could be felt above the pubes "as big as a grapefruit." Why I treated her with radium I do not know. It was in my early experience with radium and I knew no better. She was discharged a few weeks later still in very poor condition and her death within a few weeks seemed certain. For several months no notice whatever was taken of follow-up letters and finally a medical friend in her town was requested to visit the family "to get for our record the date of death." He replied, "not dead. I found her in the yard hanging up the washing." This woman has remained well and 12 years after treatment in July 1932 she was examined and found cancer free. She was well nourished and doing the usual hard work of a foreign woman the wife of a miner.

These cases surely determine the *q. e. d.* to the claim that we do cure cancer. Furthermore, these cases represent the work of 20 sometimes nearly 30, years ago. Hundreds of other surgeons were curing cancer at this time and long before as a small army of patients can attest.

Fig. 1. Miss C. G. taken on her farm at the age of 85 years, 24 years after operation for breast cancer.

Of more hopeful value still is the fact that since the patients of 20 years ago were operated on technical surgery has greatly advanced in its own field and more important still, there has been added the great advantage of radium improved roentgen technique and equipment, and the electro-knife. In some cases radiation alone has become more efficient than surgery. In most cases it is an indispensable adjunct.

Many surgeons who were producing permanent cures in the first decade of this century are still working with vastly increased experience and skill. Younger men much better trained than the older men when they began are constantly entering the lists and with the physical aids just noted the number of permanent cures in the present decade will be many times greater than for the period of 20 years ago.

END RESULTS OF RADIUM THERAPY IN 475 CASES OF CERVICAL CANCER

FLOYD E. KEENE, M.D., F.A.C.S. PHILADELPHIA

FROM 1913 to July 1926 475 cases of carcinoma of the cervix were treated with radium in the John G. Clark Clinic of the Hospital of the University of Pennsylvania. More than four-fifths of the patients presented advanced malignancy and in only about 12 per cent could the lesion be classified as belonging to Stage I.

During the period covering the early years of this report, the routine treatment consisted of 2,400 milligram hours of radium filtered by 1 millimeter of silver or 2 millimeters of brass and 2 millimeters of soft rubber tubing, with repetition of the irradiation at the end of 6 weeks. During the later years the second application was omitted, re radiation being employed only when evidence of continued growth was found. Deep X-ray therapy supplemented radium in only 5 patients. The results show that re radiation was of palliative value but it did not increase the percentage of ultimate cures.

Complete follow-up data are available in over 80 per cent of the entire series and patients not traced are classified as dead from cancer. Seventy-three patients were free from any evidence of malignancy 5 years or more after the initial treatment which represents a total salvage of 15.24 per cent. In justice to radium treatment, however, it should be stated that during the earlier years included in this report hysterectomy was performed when the lesion was operable and only the advanced cases were subjected to radium. From 1920 to 1926 both the early and the late lesions received radium treatment and in the group belonging to these years the total salvage was

18.28 per cent. Ninety two cases are classified as belonging to Stages I and II. Thirty of these, or 32.60 per cent, showed no evidence of disease 5 years or more after treatment was given. The lesions were more extensive in 383 of these, a salvage of 5 years or more was obtained in 43 or 11.22 per cent.

In the 58 patients whose lesions were classified as Stage I either radium alone or caustery amputation plus radium was used with a cure rate of 39.65 per cent the best results followed caustery amputation and irradiation, for in 34 patients thus treated 18, or 52.94 per cent, were free from evidence of malignancy more than 5 years after the initial treatment.

Specimens from 168 patients have been graded according to the classification of Martaloff. The striking feature of this analysis is the low curability rate (13.05 per cent) in the spindle cell type which is recognized as being highly radiosensitive. The best results, 26.66 per cent, were obtained in the transitional cell group. In the adenocarcinoma and the epidermoid types, the results are practically the same (17.85 per cent). It would seem, therefore, from these findings that prognostically grading according to cell type is not of much practical value.

Dissatisfied with our results, we have entirely reorganized our methods of attack during the past year. This modification consists not only in the technique of radium application, but the addition of routine roentgen therapy and the adoption of a plan whereby the problem as a whole can be more efficiently handled.

END RESULTS OF THE TREATMENT OF MALIGNANT DISEASES AT THE CLEVELAND CLINIC

GEORGE CRILE, M D., F A C S CLEVELAND OHIO

My associates Dr W E. Lower Dr T E Jones, Dr U V Portmann Dr R S Dinsmore, Dr W V Mullin, and I have seen 8,679 cases of malignant tumors of the various organs and tissues of the body. Of these, 2,756 were treated by operation only 1,399 by operation and radiation and 1,931 by radiation only and 2,593 were not suitable for treatment. Four thousand and fifty nine of the patients seen prior to 1928 have been traced. Of these, 1,182 have survived for 3 years or more and 737 for 5 years or more.

Our series includes 786 cases of cancer of the skin and subcutaneous tissues. Of these 262 were treated by operation only 75 by operation and radiation, and 360 by radiation only. Among the 215 patients seen before 1928 100 have survived for 3 years and 52 for 5 years.

We have seen 618 cases of cancer of the buccal surfaces and jaws of which 300 seen before 1928 have been traced. Among these, 94 patients have survived for 3 years and 53 for 5 years. In this series, 220 patients were treated by operation alone 165 by operation and radiation and 174 by radiation only.

Of 162 cases of cancer of the larynx 47 were treated by operation only 31 by operation and radiation, 28 by radiation alone. Fourteen patients have survived for 3 years and 9 for 5 years.

Of 292 cases of malignant diseases of the thyroid gland 79 were treated by operation alone 131 by operation and radiation, 44 by radiation only. One hundred and eighty five of these patients have been traced. Of these 55 have survived for 3 years or more and 37 for 5 years.

Of our total of 1,555 cases of cancer of the breast, 919 of those seen prior to 1928 have been traced. Of this series 437 patients have lived for 3 years and 307 for 5 years. In this series, 860 patients were treated by operation only 500 by operation and radiation, and 57 by radiation only.

We have seen 2,264 cases of malignant tumors of the gastro-intestinal tract and other abdominal

tumors which include 140 cases of tumors of the esophagus 726 of the stomach 69 of the gall bladder and ducts, and 841 of the large intestine and rectum.

Thirteen patients with carcinoma of the stomach have survived for 3 years and 7 for 5 years. Eighty nine patients with malignant tumors of the large intestine and rectum have survived for 3 years and 48 for 5 years. In the latter series 246 were treated by operation only, 78 by operation and radiation, and 142 by radiation only.

We have seen 553 cases of malignant tumors of the urinary tract 143 of the kidney 389 of the bladder 18 of the urethra and 3 of the ureters. Of the patients with tumors of the kidney 16 have survived for 3 years and 7 for 5 years. Of the patients with malignant tumors of the bladder, 150 were treated by operation only 45 by operation and radiation, and 93 by radiation alone. Of these, 47 have survived for 3 years and 30 for 5 years.

Our series includes 464 cases of malignant disease of the male reproductive organs, including 336 cases of tumors of the prostate gland. Of the patients in the latter group, 72 were treated by operation only 19 by operation and radiation, and 121 by radiation only 24 patients have lived for 3 years and 9 for 5 years or more.

We have seen 1,171 cases of malignant diseases of the female reproductive organs including 676 of the cervix and 246 of the fundus. Of the cases of cancer of the cervix 121 were treated by surgery alone 34 by surgery and radiation, and 357 by radiation alone while of the cases of cancer of the fundus 123 were treated by operation alone, 24 by operation and radiation and 63 by radiation alone. Of the patients in this total series 159 have lived for 3 years 98 for 5 years.

Exclusive of carcinoma of the jaw we have seen 176 cases of malignant disease of bone. Forty four of these were treated by surgery alone, 31 by surgery and radiation and 51 by radiation alone. Fifteen have survived for 3 years and 10 for 5 years.

REPORT ON FIFTY CASES OF FIVE YEAR CANCER CURES

DONALD GUTHRIE, M.D., F.A.C.S., BAYNE, PEPPERELL, MASS.

I WISH to report briefly upon 50 cases of 5 year cancer cures taken at random from our files the present conditions of which have been carefully investigated in a follow up clinic and found to be satisfactory.

1. Twenty-five breast cases, 8 showing axillary involvement at the time of operation. Of these 8, 2 are well 5 years 1 well 6 years 2 well 7 years 2 well 8 years and 1 well 16 years.

2. Eight cases of cancer of the cervix. One treated by panhysterectomy is well 7 years. Of 6 cases upon whom radium alone was used, 3 cases are well 7 years and 3 cases well 8 years dosage 2,400 to 5,500 milligram hours.

3. One case of cancer of the vaginal wall wore a pessary 8 years without removing it. She has been well 12 years and had 1 dose of radium 1,500 milligram hours.

4. Five cases of cancer of the body of the uterus. Of 4 treated by panhysterectomy 1 is well 5 years 2 are well 6 years and 1 is well 7 years. One treated by radium is well 8 years and had 4,800 milligram hours.

5. Four cases of cancer of the stomach. One is well 6 years 1 8 years 1 10 years and 1 20 years.

6. Five cases of cancer of the large intestine and rectum. One cancer of the ascending colon is well 17 years 1 cancer of the transverse colon with obstruction, age 18, is well 12 years 2 cancers of the sigmoid, 1 is well 16 years and 1 well 12 years.

1 cancer of the rectum age 76 is well 6 years.

7. Two cases of cancer of the bladder. One had cautery excision and radium, 1,000 milligram hours, and is well 10 years 1 had cautery excision and is well 10 years.

8. One case of cancer of the urethra had radium 1,650 milligram hours, with excision of the inguinal glands and suprapubic cystostomy and is well 10 years.

Unquestionably the campaign of education of the profession and of the laity by the various agencies upon cancer have done much to enlighten the public and cause our patients to come earlier for examination than formerly yet it is discouraging still to have many inoperable cases of cancer present themselves for relief and it is surprising today to have not a few patients request that, if the lesion proves to be cancer no attempt be made to help them by removing it. This happens frequently and one can interpret the feeling on the part of the patient in no other way except that in the minds of many there remains the firm belief that cancer cannot be cured. Reports of 5 year cures will do much to correct this misbelief and this effort of the American College of Surgeons to collect 5 year cures of cancer and publish them is indeed a noteworthy movement.

If we are to impress the laity with the fact that cancer is curable let us publish our lists of cures and let us all choose our cases for operation and radiation with greater care.

FOLLOW UP STATISTICS OF FIVE YEAR CURES IN CANCER

FRANK H. LAHEY M.D. F.A.C.S., BOSTON, MASSACHUSETTS

OF 6,535 patients operated upon for goiter 187 had definite cancer of the thyroid (2.8 per cent). We can divide all of our thyroid cancer cases into 3 groups (1) of low malignancy (2) of moderate malignancy (3) of severe malignancy. Of the patients with cancer operated upon 5 or more years ago 17 were in group one, either adenoma with blood vessel invasion or papillary adenocarcinoma. Of these, 15 are now alive and well. One could not be followed and one died 5 years after operation not of malignancy.

In group two are the cases of adenocarcinoma in which there is some hope of cure. We have 8 cases in this group one is alive over 5 years after operation and 7 are dead. Group three consists of the almost hopeless malignancies—giant cell and small cell carcinoma and fibrosarcoma. Of these there were 12 cases. One is living over 5 years and 11 are dead.

The salvation of patients with malignancy of the thyroid is in the prophylactic measure, of removing adenomata while they are still benign,

since it is in these that practically all malignancy of the thyroid arises.

We have 4 patients alive and well 5 or more years after partial gastrectomy for proved carcinoma or sarcoma of the stomach, 1 at the end of 5 years, 2 at the end of 6 years, and 1 at the end of 9 years. The salvation of patients with carcinoma of the stomach is in early bismuth X rays of the stomach in all patients with any change of digestive function, loss of appetite or distaste for food.

Of proved carcinoma of the breast, of 82 cases 28 (34 per cent) are alive and well at the end of a 5 year period. Many of these lesions have been graded as to the degree of malignancy, but time does not permit this discussion.

The salvation of patients with carcinoma of the breast lies in the frequent examination of the breasts by the patients themselves, the examination of doubtful areas by the physician or surgeon, and finally the examination by the pathologist of biopsy specimens from areas considered probably malignant by the examining physician or surgeon.

Of 47 radical resections of the colon and rectum done 5 or more years ago, representing an operability of 45 per cent, 14 (30 per cent) are alive and well now. Nine were early cases without glands, 5 showed local glands or glands in the vicinity of the growth.

The salvation of patients with carcinoma of the colon or rectum is in routine and adequate rectal examinations in all patients examined for whatever cause. In the submission of all patients who have any change whatever in colonic function to early bismuth enemas and fluoroscopy and in proctoscopy of all patients with rectal bleeding or discomfort.

Surgery had proved that it can produce lasting cures in cancer patients if the diagnosis is made early. Early diagnosis is in the hands of the family doctor and if he is to make more early diagnoses, he must do more than the sometimes merely casual examination—he must make the examination more comprehensive even then at times he will be compelled to make his diagnosis upon clinical evidence which is not always convincing but only suggestive of malignancy.

THE CURABILITY OF CANCER

NEIL JOHN MACLEAN M.D. M.R.C.S. (ENG.) F.A.C.S., F.R.C.S. (CAN.) WINNIPEG, CANADA
Associate Professor of Surgery University of Manitoba; Consulting Surgeon to the Winnipeg General Hospital

CANCER originates in a *single cell* which has taken on abnormal growth. For a certain definite period of time then cancer is a local disease and as such is amenable to cure by radical surgical measures. In assessing the curability of any given case three factors are of paramount importance: first the accessibility of the growth, second the grade of malignancy, and third, the duration and extent of the disease.

When the disease has involved parts far beyond the primary lymph nodes, cancer from the stand point of cure is practically hopeless. If every case were treated by adequate surgical methods at the onset of symptoms the percentage of cures would rise rapidly.

It goes without saying that a comprehensive knowledge of the mode of permeation of the cancer cells throughout the different organs and tissues of the body together with an exact knowledge of the lymphatic drainage of the part involved is absolutely essential to the intelligent treatment of cancer.

Two cases of epithelioma of the hand were brought to my attention some years ago. Both had been operated upon by first class surgeons, with successful removal of the local growth. Nine months later the first patient developed a mass in the axilla. Two years later the second patient developed a mass in the axilla. Both died of dissemination of the growth. It is interesting to note that in neither of these cases was the epitrochlear gland involved, the lymph drainage from the back of the hand passing directly to the axilla.

The next case I saw had had a small ulcerated nodule on the back of his hand for over a month. His family doctor had removed this nodule, and referred the case to me for further consideration because the pathologist had pronounced the growth malignant. I excised the scar widely and as deeply as possible taking away all the subcutaneous tissue down to the extensor tendons. Two weeks later the lymph glands were removed from the axilla, and radium was inserted. The

glands, though not macroscopically involved, showed cancer cells on microscopic section. This patient is alive and well 12 years later. The moral is obvious.

It would seem to be a sound surgical procedure to remove the primary lymph glands at some time subsequent to removal of the tumor. Malignant cells en route from the primary growth to the first group of filters are thus given time to reach their destinations where they are held up for some time. The lymphatic vessels do not appear to harbor cancer cells until the glands beyond are first choked and no longer able to receive their cargos from the primary growth. This later removal of lymph glands does not apply where as in the breast, a block dissection is made of all possibly involved structures.

The series of cures here presented are taken from my own private records. In every case the diagnosis was confirmed by an expert pathologist, at the time of operation. Reliable follow-up records have also been obtained in every case presented in this series. The period of freedom from cancer following operation extends from 5 to 28 years in this group.

CURED CANCER CASES—5 TO 28 YEAR CURES

	Cases	Years
Lip	8	5 to 20
Breast	36	5 to 25
Uterus	9	5 to 10
Stomach	3	7, 9 and 20
Colon and Rectum	14	5 to 25
Tongue	2	10 and 1
Ovary	2	12 and 9
Kidney	2	5 and 8
Skin of Leg		11 and 12
Skin of Hand		12
Penis	1	17
Bladder		8
Total	8	

Cancer of skin of leg and hand—2 cases cured, 1 and 12 years.

One case of cancer of the skin of the leg is of special interest. A medical man had noted an ulcer on the lateral aspect of the leg midway between the knee and ankle. It had been present 4 months and was the size of a 50 cent piece. The biopsy report was epithelioma. The ulcer was widely excised and the fascia dissected off the underlying muscle. Three weeks later the surface was skin grafted and the popliteal glands removed. No definite glandular involvement was found.

He has had no trouble now over 6 years.

Cancer of the penis—1 case, 7 year cure.

The penis was amputated 3 inches behind the corona and the inguinal glands on both sides removed 5 weeks later.

Epithelioma of the lip—3 cases of carcinoma of the upper lip living 13 and 20 years; 6 cases of carcinoma of the lower lip living 5 to 5 years.

In removing an early growth from the lower lip, a V excision is used, going 1 1/2 to 2 centimeters beyond the

demonstrable limits of the tumor. In larger growths a modification of the Dieffenbach or the Treddenberg principle is used. The submandibular and submental lymph nodes on the affected side are removed 2 weeks later, whether palpably enlarged or not. Fifty milligrams of radium screened in platinum and brass and in a rubber tube is placed in the cavity. This is moved at intervals along the length of the dissection, and taken out in from 24 to 36 hours. A modification of Dieffenbach's principle as applied to the lower lip was used in the restoration of the upper lip after removal of the tumor. It is interesting that 1 of the 3 cases of cancer of the upper lip was in a woman.

Cancer of the tongue—3 cases, 0 and 11 year cures.

The case cured 10 years had a hemiglossectomy. Two weeks later a block dissection of the glands of the neck was done on the affected side. The only gland involved was the jugulodigastric, this being the gland which, as Rutlin points out, is early involved in cancer of the tongue. It is interesting that though the growth was at the tip of the tongue the submental and submandibular glands were missed and the more remote jugulodigastric gland involved. In the other case the growth had crossed the midline in the anterior two-thirds. The glands in both submandibular regions were grossly involved and were removed at two sittings subsequent to the glossectomy. In both cases radium was used after each operation.

Cancer of the stomach—3 cases, 7, 9, and 20 year cures.

The first patient, alive and well 20 years after operation which was done in two stages. A posterior gastrojejunostomy was first done and 5 weeks later a partial gastrectomy. The 2 other cases had a Polya operation. One patient, having been well for 9 years, developed cancer in the remaining part of the stomach but at some distance from the suture line. This would seem to be a new development of cancer and not an extension of the previous growth.

Cancer of the rectum—1 patient alive and well 15 years after operation and 3 patients are alive and well 5 to 12 years after operation.

In the first patient, still alive and well 28 years after operation, the lower part of the bowel was removed by the old Kraskas method, without a preliminary colostomy. The sacral anus, without sphincteric control, has not been found to be a great inconvenience. In the second patient, alive and well 12 years after operation, a permanent left inguinal colostomy was done 18 days before the radical operation. The rectum, the perirectal and the perineal lymph nodes were removed by the sacral route, a hind part of the sigmoid being left below the colostomy. In more recent cases, the two stage abdominoperineal method was used, allowing 3 to 4 weeks between the abdominal and the sacral parts of the operation.

Cancer of the recto sigmoid—1 male alive and well 12 years after operation and 1 female died of peritonitis 11 years after operation.

In the first case, an abdominoperineal operation was done. The abdominal stage consisted of dividing the inferior mesenteric artery above its anastomotic branch to the marginal loop of the sigmoid, and mobilizing the lower part of the pelvic colon. A temporary colostomy as high up in the sigmoid as possible was then made and the abdomen closed. Not until 6 weeks later did the patient's condition seem favorable for the second stage. This consisted of wide resection of the involved part of the rectum by the transanal route, the sphincter being saved at the same time. The bowel was reunited over a rubber tube passed through the anus. The colostomy was closed some months later. This man is now in perfect health, and has a normally functioning bowel, with no sign of stricture. The second patient died 11 years and died of peritonitis.

anemia without any sign of recurrence of cancer. When I first saw her she had acute obstruction, a small perforation and spreading pelvic peritonitis. The pelvis was drained and a colostomy was established. Three months later an abdominal resection of the strictured segment was done, and the bowel reunited over a large rubber tube passed out through the anus. The colostomy was closed a month later.

Cancer of the sigmoid—4 cases, 5 to 12 year cures.

When the growth is sufficiently high up in the sigmoid to allow it to be mobilized to the surface, I have used as the method of choice, the so-called Mikulicz, or three-stage operation. If there is obstruction a rubber tube is at once "paracutaneous" into the upper part of the loop. The tumor may be left on the abdomen for a few days, or it may be removed at once, as the exigencies of the case demand.

Cancer of the caecum—1 case, female 15 year cure 1 case female, 12 year cure.

The operation performed in the first case was resection of the right colon, closure of the end of the transverse colon and an end-to-side ileocolostomy in one stage. This patient, who was only 24 years old at the time of the operation, is still in perfect health.

In the second case the ends of the ileum and transverse colon were brought out at the side. The spur was later clamped and the opening finally closed.

Cancer of the breast—9 patients, alive and well from 15 to 25 years after operation, 9 patients, alive and well from 10 to 15 years after operation and 13 patients, alive and well from 5 to 10 years after operation.

Every tumor of the breast should be regarded as cancer until proved otherwise. Even the typical mobile fibroadenoma in one of my cases turned out to be associated with a cancerous growth.

In the 9 cures ranging from 15 to 25 years, no X-ray or radium was used. During this period the tumor was removed and the incision closed. If the tumor was proved to be malignant by the pathologist a few days later the patient was taken back to the operating room and a radical operation was performed. Every attempt was made to avoid touching or re-entering the original cavity.

In the 27 cures ranging from 5 to 15 years, a rapid-section biopsy was done at the time of operation. In the management of these cases, three distinct methods of procedure were followed.

First, in cases of cancer age, with a fairly typical clinical picture of carcinoma, a radical Halstead was done immediately.

Second, in cases of cancer age where the diagnosis of carcinoma was doubtful, an amputation of the breast was done first. If the pathologist reported malignancy the radical operation was forthwith completed.

Third, in younger women with doubtful tumors the growth only was excised if reported malignant, the radical operation was then carried out.

The ideal method of procedure in doing a radical breast operation is to begin with the dissection of the axilla, and remove in one piece the lower part of the pectoralis major

the pectoralis minor, the fat, and glands from the axilla, the skin and breast including the pectoral fascia down to the ribs. It is important to include in the dissection the highest gland in the apex of the axilla under the axillary vein where it passes over the first rib into the thorax.

In this situation this gland is easily missed.

Cancer of the corpus uteri—3 cases, 5 to 16 year cures 1 case (sarcoma) 14 year cure.

In carcinoma of the body of the uterus it was formerly my practice to do an abdominal panhysterectomy. I now use the vaginal method because it can be done quite radically and with a lower operative mortality.

Cancer of the cervix uteri—5 patients alive and well 5 to 15 years after operation.

Fifty milligrams of radium (screened) was inserted into the cavity of the cervix for 24 hours. Four weeks later a radical vaginal hysterectomy was done the ureters being retracted laterally and the parametrium excised widely (Schauta operation). Radium was again used, 50 milligrams being inserted into the cavity originally occupied by the uterus, and left in for 24 hours. I now believe it best to give more intensive pre-operative radiation, and omit the immediate postoperative radiation.

Carcinoma of the bladder—1 case, 8 year cure.

The growth here was fortunately situated in the fundus. It was excised widely through a suprapubic cystotomy incision. The patient was a woman 76 years of age and lived to the age of 84 without any recurrence.

Carcinoma of the kidney—2 cases, 5 and 9 year cures.

The procedure in these cases was the usual nephrectomy plus free removal of the perinephric fat. Into the cavity left was inserted a drainage tube large enough to contain a 50 milligrams capsule of radium. The latter was left in situ for 56 hours being moved the length of the capsule at 12 hour intervals. The value of radium treatment in these cases is questionable.

Carcinoma of the ovaries—3 cases, 12 and 19 years.

Simple oophorectomy was done in each case. One patient developed carcinoma in the remaining ovary 19 years subsequent to the first. She refused further operation and finally died of general abdominal carcinomatosis.

CONCLUSIONS

1 The educational campaign by the profession among the laity for the earlier recognition of the signs suggesting cancer and immediate attention thereto, should be persisted in and extended to reach all classes.

2 Every medical teaching center should have a tumor clinic as part of its organization.

3 Some one has said that he who treats cancer should be radiologically trained and surgically minded. I would say that he who treats cancer should be surgically trained and radiologically minded.

FIVE YEAR CURES OF GYNECOLOGICAL CANCER

HOWARD C. TAYLOR, JR., NEW YORK

THE 5 year cures to be reported are drawn from the files of the gynecological service of the Roosevelt Hospital and the patients were treated during the years from 1910 through 1925. These years have witnessed fundamental changes in cancer therapy so that it is not surprising that the majority of the successful cases were treated in the latter part of this 16 year period.

The apparent improvement in results may be attributed to several factors, such as the advent of radium which was introduced into the Roosevelt clinic in 1917 and the use of the high voltage X-rays which was begun in 1924. But besides these technical innovations, there has grown up with us as elsewhere a special sense of responsibility for the patient with suspected or proved cancer. This newer attitude has manifested itself on the one hand in more conscientious efforts at early diagnosis, on the other in the organization of a follow up clinic as a check upon the efficiency of treatment.

The Roosevelt gynecological service treats on an average about 40 cases of cancer in a year. Its radiological equipment is limited to 140 milligrams of radium and a single high voltage X-ray machine. It is probable that a majority of cancer cases throughout the country are treated in institutions of about this size, so that the rate of cures I shall report may be taken as typical of that which widely prevails throughout the United States or is at least readily attainable.

Before reporting 5 year cures let me state that pathological reports giving confirmation of the diagnosis are on file at the hospital for all of these cases and for all but a few the microscopic slides have been reviewed and the diagnosis verified within the last 2 years.

The treatment of cancer of the cervix has varied greatly over the period noted so that cures must be reported upon special groups dependent upon the type of treatment. From 1910 to 1916 the only significant treatment for cervical cancer was hysterectomy. In these years a total of 126 cases of all stages of the disease were observed. Nine 5 year cures resulted. (For the 113 primary cases, the operability rate was 60 per cent, the absolute 5 year cure rate 7.1 per cent.) Two patients of this period are known to have been living and well 18 and 20 years, respectively after their operations.

From 1917 to 1920 when radium was first being used, either alone in the advanced cases or as a preliminary to hysterectomy 84 cases were treated, with 5 year cures in 11. (For the 78 primary cases the operability was 43 per cent, the absolute 5 year cure rate 14.1 per cent.)

From 1921 to 1923 radium was given increasing scope and the indication for hysterectomy was further restricted. Forty three cases were treated, with 11 cures. (For the 37 primary cases the operability rate was 27 per cent, the absolute 5 year cure rate 29.7 per cent.)

In the years 1924 and 1925 when radium was used almost exclusively 46 cases were treated, with 5 year cures in 8. (The absolute 5 year cure rate for the primary cases was 18 per cent.)

The cases of carcinoma of the corpus have been treated more or less uniformly throughout the period and only one fifth of the primary cases were regarded as inoperable. Of the total of 90 primary and recurrent cases there are 22 known cures. (This represents an absolute 5 year cure rate of 25.8 per cent in the 85 primary cases.)

The cases of carcinoma of the ovary can also be reported as a single group but offer a discouraging figure since only 5 cases out of a total of 66 are known to have been well after 5 years. (The 5 year cure rate for the 58 primary cases was 8.6 per cent.)

Among the less common forms of gynecological cancer there can be reported 5 year cures in 4 among 17 cases of cancer of the vulva and 1 in 7 cases of vaginal cancer. Among a miscellaneous group consisting of 1 case of primary tubal cancer, 3 cases of chorio-epithelioma, 3 cases of myosarcoma of the uterus, 4 cases of sarcoma of the ovary and 16 cases of generalized peritoneal carcinoma of undetermined origin there were no cures.

To summarize, the Roosevelt clinic has to offer the following 5 year cures

TABLE 1.—TOTAL FIVE YEAR CURES

	5 year cures	Total cases
Cancer of the cervix	39	300
Cancer of the corpus	11	60
Cancer of the ovary	5	66
Cancer of the vulva	4	17
Cancer of the vagina	1	7
Miscellaneous	0	37
Total	71	506

TABLE II—EXTENT OF DISEASE WHEN TREATMENT WAS INSTITUTED

	Early		Intermediate		Advanced	
	Total cases	Percent ages	Total cases	Percent ages	Total cases	Percent ages
Cervix	24	8	31	17	224	75
Corpus	26	29	27	30	37	41
Ovary	9	14	16	24	41	62
Vulva	19	53	7	41	1	6
Vagina	1	14	0	0	6	86
Miscellaneous	0	0	1	4	26	96
Total	60	14	102	30	335	66

The total number of cancer cases treated in these years was 506 so that it may be said that approximately 1 woman in 7 who came for treatment was well for at least 5 years after her treatment.

The figure of 1 in 7 represents an absolute minimum inclusive of all advanced and recurrent cases, and with the acceptance as failures of all cases that could not be traced. Table II giving a somewhat arbitrary division of cases according to the extent of the disease, shows that almost two-thirds of the cases were advanced when they first came for treatment. From this table it becomes clear that the unfavorable character of

TABLE III—PERCENTAGE OF FIVE YEAR CURES AMONG TRACED CASES IN DIFFERENT STAGES OF THE DISEASE

	Early	Intermediate	Advanced
Cervix	75	41	8
Corpus	63	50	0
Ovary	33	31	0
Vulva	50	0	0
Miscellaneous	100	0	0
Total	63	37	5

cancer statistics is of course determined by the vast preponderance of the late and unfavorable cases.

A more encouraging outlook is obtained from Table III which shows that 5 year cures may be hoped for in over one half of the early and in over one third of the intermediate cases.

The failure of efforts to reduce more materially the percentage of patients who come for treatment in an advanced stage of the disease is a discouraging aspect of the present status of cancer control but the relatively great success being obtained in the treatment of the favorable cases remains a strong incentive to continued striving for earlier diagnosis.

CANCER OF THE CERVIX AND CANCER OF THE BREAST

FIVE YEAR END-RESULTS IN THE UNIVERSITY OF CALIFORNIA HOSPITAL

FRANK W. LYNCH, M.D., F.A.C.S. AND EDWIN I. BARTLETT, M.D., F.A.C.S., SAN FRANCISCO, CALIFORNIA

THIS is a summary of the 5 year cures in a series of 222 cases of proved carcinoma of the cervix treated in the University of California Hospital between March 16 1916, and September 30 1927. No case has been lost in the follow-up since treatment. Seven patients died of intercurrent disease during the 5 year observation and 4 died following surgery. These are charged as cancer deaths.

The cases are grouped into the four stages adopted by the American College of Surgeons.

Stage I. Cancer limited to the cervix.

Stage II. The cancer may have reached one or the other of the vaginal fornices but there is no demonstrable extension to the parametrium. The uterus is still mobile.

Stage III. The cancer has extended beyond the cervix and definitely invaded the parametrium. The uterus is fixed.

Stage IV. The cancer forms a mass which fills the pelvis, may have grown down on the vaginal walls, may or may not have metastasized, and represents the last stages of the disease.

Stage V. Recurrent cases.

Type of material. The series comprises 185 cases in which the cancer was first treated by me (Lynch) and of 37 in which a hysterectomy was done by others and radiated subsequently by me either as prophylaxis or as treatment of known recurrence.

Results of treatment. Stage I. Of the 19 cases, 17 are living and well 5 years after treatment. There were two intercurrent deaths charged as cancer. One died from a paralytic stroke 5 months after surgery and 1 of heart disease 4 years after radium treatment. Symptomatic cancer was found in the latter patient at autopsy in both the right and left hypogastric glands. The cure for this group is 89.5 per cent.

Stage II. Of the 32 cases, 13 were living and well at the end of the 5 year observation period, a cure of 40.6 per cent.

Stage III comprises 85 cases with only 11 survivors, a cure of 12.8 per cent.

Stage IV consists of 49 cases. No five year survivors. Forty four of the 49 died within the

Chart 1. Cancers of uterine cervix.

Chart 4. Carcinoma of the cervix, 111 cases.

first year and all but one within a year and 3 months. The extremely large percentage which cures of this stage form of all inoperable cases reduces the total cure of the inoperable cases to figures less than those from other clinics that had learned earlier than we that it is useless to treat them.

Stage V. Of 37 patients of this group 4 were 5 year survivors a percentage of 10.8.

SUMMARY

The 5 year cure for the entire series is 20.3 per cent including those in Stage V or 22.2 per cent for the 185 patients for whose first treatment we were responsible.

Combining the cases in Stages I and II we find 5 year cures of 58.8 per cent for this early and "borderline as to operability" group.

Combining the 85 Stage III and 49 Stage IV cancers we find a cure of 8.2 per cent.

The entire series consists of 222 treated cases with 45 survivors.

CONCLUSIONS

This study shows that a cure may be confidently expected in early cervical cases following proper treatment.

Chart 5. Carcinoma of the breast, Group A1: 39 cases, primary without axillary metastases, local conditions favorable.

Chart 6. Carcinoma of the breast, Group A2: 14 cases, primary without axillary metastases, but with unfavorable local conditions, such as large tumor, tumor in an inner quadrant, etc.

Death—surgical	1	
Death—cancer	81	
Living and well	50	32
Living—recurrence	11	7

CARCINOMA OF THE BREAST

This is a summary of the 5 year results in 156 cases of carcinoma of the male and female breast treated at the University of California Hospital between January 1, 1918 and October 1, 1927. The cases have been placed in four groups, according to prognosis as judged by the operative finding.

Group A1 includes primary cases without axillary metastases and with favorable local conditions such as small tumor, tumor in an outer quadrant, etc.

Chart 7. Carcinoma of the breast, Group B1: 34 cases, primary with metastases, local conditions favorable.

Chart 8. Carcinoma of the breast, Group B2: 69 cases, primary carcinoma with metastases and with unfavorable local conditions, extensive involvement, inner half, etc. Recurrent carcinoma, limited involvement, no evidence of general disease.

Chart 9. Five year results in 150 cases of carcinoma of breast.

Group A2 includes cases also without axillary metastases, but with unfavorable local conditions, such as large tumor, tumor in an inner quadrant, etc.

Group B1 includes primary cases with axillary metastases but with favorable local conditions.

Group B2 includes also primary cases with axillary metastases but with unfavorable local conditions, and also secondary cases without evidence of general disease or extension of disease externally beyond surgical reach.

Material. The series comprises 93 cases treated by me (Bartlett) and 63 cases treated by several others. All had a radical operation, and all of mine were treated by the method which I have previously described.¹

Results of treatment. Group A1. Of the 39 cases treated, 30 are well after 5 years, thus making 78 per cent cured. Of the 9 charged against cancer death, 3 were lost in the first year, 1 died of bronchopneumonia in the second year

and 1 died of pernicious anemia, without any trace of cancer in the third year after treatment. Four actually died of cancer.

Group A2. Of the 14 cases treated, 6 are well 5 years after treatment, thus making 43 per cent cured. All the deaths were due to cancer. This illustrates the increased mortality from cancer in an inner quadrant.

Group B1. Of the 34 cases treated, 9 are living and well 5 years after treatment, thus making 26 per cent cured. Out of the 25 charged against cancer death, 3 were lost, thus 22 actually died of cancer.

Group B2. Of the 69 cases treated, 5 are living and well 5 years after treatment, thus making 7 per cent cured. Of the 64 charged against cancer death, 5 were lost, 1 died following operation, and 2 died of intercurrent disease, thus making 58 who actually died of cancer.

SUMMARY

There were 5 year cures in 32 per cent of the entire series. The life expectancy in Group A1 (with favorable local conditions and without axillary metastases) is nearly twice as good as that in Group A2 (where the local conditions are unfavorable) and is three times as good as in Group B1 (which had the same favorable local conditions but with axillary metastases). The life expectancy in the groups without metastases (A1 and A2) is double that of B1 alone. If we exclude Group B2 in which the majority of cases gave no hope of cure from the clinical findings alone, the hopeful clinical case with or without metastases should have a 50 per cent chance of cure.

CANCER OF THE CERVIX UTERI

STATISTICAL STUDY OF ONE THOUSAND FIVE HUNDRED AND SEVENTY EIGHT PATIENTS
TREATED AT THE HOWARD A. KELLY HOSPITAL BETWEEN JANUARY 1 1911 AND
SEPTEMBER 30 1927¹

CURTIS F. BURNAM M.D. F.A.C.S., BALTIMORE, MARYLAND

CANCER of the uterine cervix when treated in its incipency is curable in nearly every case. The possibilities of cure steadily diminish as the disease advances until it becomes an incurable and fatal malady.

A review of the records upon which this paper is based demonstrates that a considerable proportion of the hopeless and far advanced cases are in these stages because of the ignorance and carelessness not only of the patient, but frequently of her medical advisers.

While the methods of employing existing means of treatment are steadily being improved it is evident that more can be gained in treating this disease by education which will bring patients in for treatment during the earlier stages of the cancer. At this writing about 50 per cent of the cases which present themselves for treatment at The Johns Hopkins Hospital are operable but only a very small proportion of these are in the very early stage in which the disease is limited to the cervix.

In order to study the results obtained by treatment of the 1578 cases which presented themselves in the period between January 1 1911 and October 1 1927 they have been grouped under five distinct headings: operable, prophylactic, inoperable, recurrent and palliative.

At this hospital the principal method of treatment has been by radium and secondarily by surgery and X-ray. The relatively small percentage of operable cases is due to the fact that the sources from which these cases came during these years, principally relied on surgical methods alone in the treatment of the operable cases coming to them. Slightly over 13 per cent of all cases treated have been early enough to be classified as operable.

In addition to the anatomical extent of the disease the results are dependent upon technique employed in treating and upon the type and grade of malignancy found on microscopical examination. Time does not permit, however, of a consideration of the influence of these factors upon the 5 year cure rate.

Let us now consider the five headings under which our cases are grouped:

Operable cases. Under this caption are included all the stages except those presenting firm fixation through the parametrial and paravaginal tissues to the pelvic wall and those with definite palpable glandular metastases. It comprises not only the operable but borderline cases. It includes the vaginal extensions no matter how extensive and the parametrial involvements which do not extend as far as firm fixation to the pelvic wall. All of these cases are cases treated with radium or radium and X-ray.

Prophylactic cases. These cases represent the same extent of trouble or perhaps a little less than in the first group. They are differentiated because they were first treated by surgical removal and then by postoperative radiation.

Inoperable cases. Under this caption are included all those cases which present firm fixation to either one or both pelvic walls through the parametrial or paravaginal tissues. Most of these patients presented extensive vaginal extensions of the disease. Excluded from this group are cases with general or with demonstrable extensive local glandular involvement.

Recurrent cases. Under this title are included all recurrences which have followed the surgical removal of the uterus for cancer of the cervix. In these cases the extent of the disease present at the time of treatment varied greatly.

Palliative cases. Under this caption are placed all cases showing general metastases or extensive local glandular metastases. Most of them have been associated with massive local fixation. The treatment given has been not to cure but to stop bleeding or to alleviate pain.

THE RESULTS OF TREATMENT

In Table I is shown by years, the total number of cases treated, the total number of cures and the percentage of cures for cases treated and then the total group is divided into the five divisions indicated and for each group the number of cases, the number of cures and the percentage of cures are shown. This table refers to 5 year cures. No case is included except when 5 full years have elapsed from the time of treatment and when most careful clinical examination demonstrates no

¹These cases were all treated by Howard A. Kelly, William Neill, and the author at The Howard A. Kelly Hospital, and most of them have been seen by at least two of us.

TABLE I.—DISTRIBUTION OF CASES FROM
JANUARY 1 1911 TO OCTOBER 1, 1927

Total Number of Five Year Cases and Percentages in the Different Groups

	Total cases	Cured cases N %	Operative N %	Presby- lamin No %	In- operable No. %	Recu- red No %	Prob- ably cured No.

1917	64	10 10 00	100	100	17	1	0
1918	73	10 10	100	100	100	100	100

trace of the disease. The cases of patients dying from other causes than cancer as well as all the cases of patients who have not been traced are placed in the uncured class. In our entire series, there are 41 cases in which a clinical cure was known to be present for several years, but, as yet, we have been unable to trace the patients and make sure of the final result. Of these 41 cases 22 were inoperable, 9 were operable, 5 were recurrent, and 5 prophylactic. The variations in per centages of cures depend in part, on the distribution as to extent of disease in part, perhaps on the varying techniques employed and, in part, on the types and grades of malignancy. It beautifully demonstrates, however the limitations

TABLE II — COMBINATION OF ENTIRE 1578
CASES SHOWN IN TABLE I

	Cases	Cure	Per cent
Cured		258	75 per cent

Dying of other forms of cancer from birth to death

Dying of other disease

Followed for 7 years or longer and now being treated

The oldest cured cases I well for 21 years—2 of them extensive borderline, and 1 extensive recurrent.

which must be put on drawing deductions from a small series of cases, such as is presented by any one year.

In Table II are shown the combined results of the entire series of cases, as well as the results obtained in each of the five groups for the 5 year period. In addition, the relative percentage frequencies of each of the five groups is shown, and also the 10 year results on the cases which were well at the end of 5 years. Finally the results are given in the cases treated in 1911 which was the first year of this series.

While 5 years is an arbitrarily accepted standard for a cure, it must be constantly kept in mind that recurrences may take place after this period. However it is of interest that we have had only one recurrence after 10 years, and this might be interpreted as a primary new-growth, as it occurred in the lungs. Taking the period prior to October 1, 1922 there were 150 5 year cure cases. At the end of 10 years only 110 were still living and well as shown by examination. Of the 40 cases remaining 16 died of recurrences between the sixth and tenth year; 5 died of cancers of a different type developing *ab novo*. It may be of interest here to mention 2 cases, in 1 of which the patient was cured of a cervical cancer for 10 years, and is now cured of a breast cancer for 4 years; the second was cured of a cervical cancer for 6 years, and of an uterine cancer for 3 years.

Fifteen patients who were traced from periods varying from 7 to 10 years, have been temporarily lost sight of. Six cases after the 5 year period died of other causes than cancer.

It is of interest that the 3 cured cases of the year 1911, 21 years ago are all still well. Two were extensive borderline operable cases and one an extensive recurrent case.

CANCER OF THE PELVIC ORGANS

W. E. CALDWELL, M.D. F.A.C.S., New York

THE experience of a general hospital with a gynecological service would seem to be instructive. In the Sloane Hospital up to 1929 cancer of the female reproductive organs was treated as part of the regular routine service. Those requiring operative treatment were skillfully handled. Those requiring other forms of treatment radiotherapeutic electrical and heat, were handled according to the intensity with which the particular therapist happened to have studied that particular field. In cancer of the cervix experience with radium is of interest. The follow up studies show a 5 year cure in 7 cases of 21 or 33 1/2 per cent of those in which the process was limited to the uterus but in those in which the process had spread to the vagina or broad ligaments in only 16 cases of 94 or 6 per cent. (All patients not followed are classed as dead.) In reviewing the dosage of radium, the greatest variety is seen varying from one barely sufficient to produce an artificial menopause to one which according to present standards would be considered adequate. Similarly the study of the follow up statistics of these cases shows a great unsatisfactory variation. Those physicians who were interested obtained results far superior to those who treated women merely as a part of the routine.

In 1929 a group was organized within the Department of Obstetrics and Gynecology composed of two members of the staff who co-operate with the Department of Pathology and the Department of Radiotherapy. Into their hands was placed the responsibility for all radium treat-

ment and the pre-operative and postoperative conduct of the cases. Since this time the operative treatment has gone on as before. The efficacy of the radium treatment on the other hand as indicated by the 3 year results has advanced greatly and the follow up clinic shows a return of 95 per cent.

The moral from this experience is that the treatment of a disease such as cancer of insidious onset and prolonged course whether favorable or unfavorable requires an interested group equipped to carry out any diagnostic procedure or any therapy, and organized to maintain constant contact with a cancer patient from the time such a condition is suspected. Whether this group should function as a subgroup under one of the therapeutic specialties as radiotherapeutics or of a cancer clinic or on the other hand as a subgroup of the gynecological department is a matter of debate. In this disease it is felt that above all else early diagnosis is important and that by having the gynecological cancer cases diagnosed and followed in the gynecological clinic, the losses caused by the referring of the patient from one department to another will be minimized and the patients brought earlier to treatment. Moreover the treatments themselves are within limits fairly well standardized. Operative techniques have varied very little for many years. The use of radium as developed in different centers in many parts of the world has gradually worked out so that the principles of the techniques are fundamentally the same and the results in large groups show unimportant variations.

RESULTS OF TREATMENT OF CANCER OF THE UTERUS AT THE MASSACHUSETTS GENERAL HOSPITAL

LINCOLN DAVIS, M.D., F.A.C.S., BOSTON, MASSACHUSETTS

I AM glad to take part in a symposium on cases of cured cancer for I am sure that in spite of all the good work done by various organizations in spreading a note of hopefulness in the treatment of cancer there is still a very widespread feeling that the disease is hopeless and incurable. This feeling exists not only among the laity but also with many general practitioners. Each of the latter sees relatively few cases in his own practice, and if there happen to be a consecutive number of bad results naturally the practitioner becomes pessimistic about the situation. If large series of cases are analyzed however it is found that there is a very respectable percentage of arrests of the disease or cures.

With the laity the situation is even worse. The average person is fond of talking about his or her operation but I have never heard any one talk about having had an operation for cancer. As a matter of fact the patient is usually entirely unaware of the existence of the disease in his own case the secret having been carefully guarded by the doctor as well as by relatives and friends. This was forcefully brought home to me a number of years ago when in talking with a friend a very intelligent man and a prominent attorney I told him that I had been giving a talk on cancer. He said, "As a matter of fact, has a case of cancer ever been cured?" This man himself had been operated on some 15 years previously for cancer of the sigmoid flexure, by the late John W. Elliott of Boston, who performed an entirely successful removal with suture of the bowel. However this highly intelligent and generally well informed man was entirely unaware of the fact that he himself represented a cure of a very malignant form of cancer of the bowel. On the other hand when a patient succumbs after an operation or following a long illness it is quite generally circulated that "poor so and so had cancer." So that the brilliant results are carefully hidden while the fatal cases are thoroughly discussed. Therefore I think the American College of Surgeons is to be thoroughly commended for persistently keeping this aspect of the subject before the profession and the public.

I am convinced that a large number of cases of cancer have been cured in the past, a still larger number are being cured at the present time and even greater prospects lie before us in the future.

I wish to present a brief report of the results of treatment of cancer of the uterus at the Massachusetts General Hospital. These results may not seem brilliant the figures are not perhaps as large as one might expect but it should be remembered that this is a general hospital specializing in no way in gynecology. In fact for several years following the year 1922 when it began to become evident that the results of radium treatment of cancer of the cervix were at least as good if not better than the results following radical operation patients with this disease at the General Hospital were as a rule referred to other institutions for treatment, as the Massachusetts General at that time had no radium. It was not until the year 1925 that radium treatment of cancer of the cervix was begun on a very small scale, so that the opportunities for reporting 5 year "cures" following its use are extremely limited. Nevertheless, the results have been distinctly heartening encouraging us to continue and increase its use with substantial abandonment of hysterectomy. The next few years will show whether or not our confidence has been well founded.

The standard of cure generally adopted in compiling cancer statistics, the so called 5 year cure, consists of an observation period of 5 years following treatment, at the end of which time the patient is living without discoverable signs of the disease. This standard has been followed in this report but it should, of course, be understood that the term is used in a relative rather than an absolute sense, and that the period of 5 years merely represents a lapse of time which indicates that future recurrence is relatively unlikely. Recurrences are most frequent in the first 2 years after treatment, and progressively diminish thereafter. Three years has been proved an insufficient period of observation. Recurrences, unfortunately do take place after 5 years or even after 10 or 20 years, or at any period.

In this report 4 patients, who have been included among the cured cases, having been reported living and well at the end of 5 years, died of undoubted recurrence at the end of 6, 7, 8, and 15 years, respectively. On the other hand, 3 patients reported well by letter at the end of 5 years who died of abdominal metastases early in the sixth year are not included. If an absolute cri-

tion of cure were demanded it would be necessary to establish the freedom of the body from recurrence by a complete autopsy after the death of the individual an obvious absurdity.

Interest in the operative treatment of cancer of the cervix at the Massachusetts General Hospital started in 1901 when Dr Farrar Cobb began doing a modified Wertheim operation. He later was given the assignment of all cases in the hospital. In 1920¹ Dr Cobb made a report of his results with the radical operation showing 5 year cures in 11 of 26 cases, or 42 per cent.

In 1915 the assignment of the operative treatment of cancer of the cervix came into my hands. I reported before the American Surgical Association in 1922² the end results of my work with the radical operation showing 8 cases of survival of 5 years or more without recurrence in 20 cases followed up or 40 per cent.

In 1925 as before stated we began the use of radium at the hospital in a small way at first only for the advanced cases of carcinoma of the cervix. Gradually however radium supplanted radical operation in the treatment of the more favorable cases and only two radical Wertheim hysterectomies have been done since 1925.

I have personally performed a total of 43 hysterectomies for cancer of the cervix at the General Hospital. Four of these patients have not been traced. Of these 43 proved cancer cases 16 patients survived the operation for 5 years without signs of recurrence or 37 per cent. Two patients have survived for 16 years and are in good health today. One of these showed definite invasion of the parametrial tissue removed.

The radium cases are limited in number and comprise 11 cases of 5 year cures. The earliest of these was treated in July 1925. There were 2 cases in which radical hysterectomy was preceded by radium treatment. One of these resulted in a cure which has been credited perhaps somewhat arbitrarily to the hysterectomy.

In estimating the value of any form of treatment it is important to know what proportion the successful cases bear to the whole number seen or treated. In 1925 there were 15 cases of carcinoma of the cervix treated with radium with 5 cases of 5 year cures. In 1926 there were 24 cases treated with 2 cases of 5 year cures. In 1927 up to September there were 25 cases with 4 cases of 5 year cures. Altogether 64 cases were treated with radium with 11 cases of 5 year cures or 17 per cent. There was no selection of cases only the moribund were excluded.

An analysis of the records of patients operated upon by me personally shows that something over 30 per cent of all cases seen were subjected to radical operation. A percentage that was perhaps unduly high for the best operative results. In the 42 radical abdominal hysterectomies and 1 vaginal hysterectomy there were 4 operative deaths a mortality of 9.5 per cent. There has been no mortality in the cases treated with radium.

Cases of adenocarcinoma of the body of the uterus have been treated by hysterectomy as a first choice radium being used only if distinct contra indication to a major operation existed. In carcinoma of the body of the uterus as contrasted with carcinoma of the cervix the operability rate is relatively high and the mortality rate relatively low. Furthermore the disease is of relatively slow growth metastasizing outside the uterus at a late stage so that the total abdominal operation gives exceedingly good results superior in our hands to the application of radium which involves some danger of perforation or hemorrhage and at best is a blind procedure.

In an analysis of 50 cases of adenocarcinoma of the body of the uterus at the Massachusetts General Hospital made in 1925³ I found over 60 per cent of 5 year cures. This compares favorably with the results of the treatment of cancer anywhere in the body excepting only superficial lesions of the skin.

During the past year Dr J V Meigs has undertaken an intensive follow up study of all the cases of cancer of the uterus at the hospital during the last 20 years, checking up and reviewing the pathological specimens and throwing out all doubtful cases and all cases in which the pathological specimens have been lost, also personally examining surviving patients. A few cases recorded as cures in previous reports have been excluded in this rigid review. The follow up has not yet been completed and it is fair to expect that some additional cures will be found. I am greatly indebted to Dr Meigs for the use of his data.

As a result of this review to date it is found that there are at the Massachusetts General Hospital complete records of 64 women who had microscopically proved cancer of the uterus who have survived treatment for at least 5 years without signs of recurrence so called 5 year cures. Of these patients 34 had carcinoma of the cervix, and of these 23 had radical hysterectomies and 11 were treated with radium. Thirty patients had carcinoma of the body of the uterus of these 28 were treated by hysterectomy either vaginal

or abdominal, and 2 were treated with radium. Slightly over one-half of these cases were personal

ones, the others were treated by colleagues on the hospital staff

GYNECOLOGICAL CANCER

W. A. G. BAULD M.D. F.A.C.S., MONTREAL, CANADA

ON the plea of this College to establish a faith in the curability of cancer in the minds of the medical profession and the public in general, I come to add a contribution from the Royal Victoria Montreal Maternity Hospital Montreal Canada

The figures I regret are small but represent the first series available over the prescribed 5 year period. The percentage cured and remaining well in this series is 26.6 (4 out of 15).

The care of the cancer patient applying to a large gynecological clinic offers peculiar and special difficulties. We have all seen the sacrifices to inexperienced treatment—the fatal delay in the undiagnosed case—the careless patient who does not follow advice and must be searched out and driven in when delinquent and who will return only on the appearance of urgent and late symptoms. We all know the neglected and pitiful state of the dying cancer patient and we all know how easily they fall prey to the designs of unscrupulous cancer cure schemes. They require guidance and protection as well as treatment and comfort.

While all will admit the benefits accruing from large and specialized cancer clinics with every facility for treatment and research it is not yet possible for these institutions to reach all the sufferers first hand and frequently the best chance is lost through inexperienced and damaging or incomplete treatment.

There remain of necessity a great number of patients who must be treated in the clinics of their vicinity and it was these factors which stimulated the formation of a subdivision of our main gynecological department under what is known as the Cancer Clinic and from which these results come.

A few words of the formation and activities of this unit I think, may be of some assistance to those similarly situated. The immediate direction of the unit was placed under one member of the

existing general staff trained and practicing gynecology in all its branches. He was required to make a special study of gynecological cancer in all its phases and the most efficient methods of treatment—needless to say this implied a study of radium and other radiological methods and their appropriate uses. To the group was added a second member of the staff with special training in laboratory methods and pathology so bringing this important factor into intimate interest with the problems. This move has proved extremely valuable in the clinical work.

An adequate supply of radium was provided for the work and the care and use of the radium is entrusted to the members of this subgroup. This I believe important to insure the safe and proper use of radium when required for cases other than cancer.

Accessible X-ray facilities are available through the main hospital X-ray department but with an increased growth of the clinic it is evident that suitable and special apparatus may be advantageously placed near the special clinic.

Records and follow up comprise a most important branch of the work and requires unusual interest and fidelity to the work. I am happy to tell you that this work has been well done and that only 8 of a total of 228 during the activities of the clinic have escaped observation over a period of 6 years.

In conclusion may I emphasize the following points:

1. Cancer patients applying to a gynecological clinic should be segregated into a special clinic.

2. This clinic should be under the direction of a clinician who has special knowledge and experience in radiological methods.

3. Special records and an accurate follow-up are vital to results.

4. Results may be obtained equal to the larger and more favorably equipped special cancer clinics.

CANCER OF THE BREAST

J M T FINNEY MD F.A.C.S. BALTIMORE MARYLAND

WHEN a woman consults a surgeon for a lump in her breast, one question and one only of paramount importance at once presents itself to the surgeon for answer namely Is this lump cancer or is it not? All other questions but this can await an answer. This one cannot, and until it has been answered beyond all question of doubt, the first duty of the surgeon to his patient will not have been discharged. As soon as the diagnosis of malignancy has been definitely determined the combined judgment of experienced surgeons and pathologists demands the immediate removal *en masse* by surgical operation of the entire breast and all adjacent structures that may possibly be invaded by the growth. Until complete extirpation with a wide margin by clean dissection of all suspicious tissues has been accomplished the second great obligation of the surgeon to the patient with cancer of the breast will not have been discharged. In the present state of our knowledge there can be no possible excuse for failure to recognize cancer of the breast or to apply promptly the only effectual remedy namely its radical removal as described by Halsted in his epoch making communication in 1894.

That cancer of the breast as elsewhere is curable and that cancer of certain types and in certain regions of the body is more amenable to treatment than in others are established facts. Because it is not a vital organ and owing to its anatomical structure the breast lends itself readily to thorough examination and complete removal. The one thing yet lacking in securing the maximum number of cures is the active intelligent co-operation of the patient. She must, somehow be impressed with the absolute necessity of consulting her physician at the first sign of any trouble in the breast. This is the crux of the whole matter.

My contribution to this discussion is based upon a study recently made by Lewis and Rieholf of 950 consecutive cases of cancer of the breast many of them my own operated upon in the Johns Hopkins Hospital over a period of 42 years from the beginning of the hospital in 1889 to 1931 by 38 different surgeons. Of this number 517 cases operated upon more than 5 years have been traced and their present condition is known. Of this number 135 (26 per cent) lived from 5 to 32 years following operation. While this percentage of cures compares favorably with other statistical studies it must not be forgotten that over 50 per cent of the cases were operated upon by members of the resident staff and that the period covered runs back to the very beginning of the Halsted operation when cases were very late in coming to operation.

The recital of these results will at once suggest to the mind of every thoughtful surgeon two ideas (1) how comparatively small is the number of cures obtained and (2) the query. By what means may this number be materially increased?

Four significant facts emerge from a symposium such as this (1) That cancer is curable or what amounts almost to the same thing it may be held in abeyance for an indefinite term of years by timely radical surgical measures (2) That early diagnosis is essential to success. (3) That the most radical excision of the growth is alone productive of the best results. (4) That in the present state of our knowledge any improvement in our percentage of cures must come through educating the patient to seek earlier advice. The physician is not always blameless in failing to refer his patient at once to a competent surgeon and the surgeon himself is not always sufficiently radical in his removal of tissues to give the patient her best chance. In all three of these directions improvement may be made.

CARCINOMA OF THE CERVIX UTERI

COMBINED STATISTICS OF PATIENTS TREATED IN THE CANCER CLINIC OF THE WOMAN'S HOSPITAL IN NEW YORK SERIES FROM 1919-1927 WITH A FIVE YEAR OBSERVATION PERIOD

GEORGE GRAY WARD M.D., F.A.C.S. NEW YORK

WE have previously published statistical reports of the 5 year results we have obtained with radiotherapy of carcinoma of the cervix uteri at the Woman's Hospital in 1925, 1928 and 1930. We now have two more 5 year series to report making 6 series in all covering a period of thirteen years.

During this time I have had under my direction some 500 odd cases of cancer of the cervix and more than 100 cases of carcinoma of the fundus. There are 3 cases of the cervix in which the 5 year observation period has been completed and this group forms the basis for this statistical report.

The important features of our technique as previously published are a personal follow up each month of all cases throughout the 5 year period as far as is possible, the employment of blood transfusions before or shortly following radiotherapy in all anemic or cachectic patients, and the re-irradiation of metastatic recurrences in the vaginal tract in their incipency when discovered in the follow up clinic. Our initial dosage averages from 3,600 to 4,200 milligram hours of radium element.

The results recorded in this report include 98 cases of the last two 5 year series from May 15, 1923 to May 15, 1927. The complete statistics of the 5 year end-results of all cases of carcinoma of the cervix uteri treated at the Woman's Hospital from February 25, 1919 to May 15, 1927 or a total of eight series, is shown in the following tables. This includes the 14 patients who were refused radium treatment because the growth was too far advanced.

TABLE I.—CASES OF CARCINOMA OF CERVIX SUITABLE FOR RADIUM THERAPY

	Number	Per cent of total
Total cases seen	357	100.0
Cases treated with radium	343	96.1
Cases refused radium	14	3.9
Radium operability—96.1 per cent		

Table II shows that 21.6 per cent of the total number of cases were operable (limited to the cervix) whereas 8.4 per cent were inoperable (extended beyond the cervix).

TABLE II.—OPERABILITY IN CASES OF CARCINOMA OF CERVIX

	Number	Per cent of total
Total	357	100.0
Operable—limited to cervix	77	21.6
Class I Schmitz	4	1.1
Class II Schmitz	73	20.5
Inoperable—extended beyond cervix	280	78.4
Class III Schmitz Stages II & III	240	67.2
Class IV Schmitz Stage IV	40	11.2

TABLE III.—AGES OF CARCINOMA OF CERVIX PATIENTS

Years	Number	Per cent of total
20 to 30 years	18	5.0
30 to 40	71	19.9
40 to 50	121	33.9
50 to 60	94	26.3
60 to 70	40	11.2
70 to 80	13	3.6
80 to 90	2	.6
	357	100.0

Youngest 14 years

Oldest 80 years

Five per cent of the patients were under 30 years of age

TABLE IV.—PRIMARY MORTALITY OF RADIUM TREATMENT FOR CARCINOMA OF CERVIX

	Radium applicator cases	Deaths per 100 applicator cases	Deaths per 100 cases
Total	357	6	1.7
Class I Schmitz	4	0	0
Class II Schmitz	73	0	0
Class III Schmitz Stages II & III	240	3	1.2
Class IV Schmitz Stage IV	40	3	7.5

The primary mortality for all cases treated was 1.7 per cent with no deaths in the Class I or Class II (Schmitz Class) (League Nations Stage I cases).

TABLE V.—CARCINOMA OF CERVIX FOLLOWING SUPRAVAGINAL HYSTERECTOMY

Derived from total of 357 cases

Number	19
Living 5 years	3
Per cent	42.11

TABLE VI—FIVE YEAR END-RESULTS IN CASES TREATED FOR CARCINOMA OF CERVIX

Grouped according to Schmitz Classification of Extent of Disease

Class	Number	Living	Per cent living 5 years
I	4	2	50.0
II	73	36	49.3
III	240	47	19.6
IV	17	0	0
Total	343	85	24.8

TABLE VII—FIVE YEAR END-RESULTS IN PATIENTS TREATED FOR CARCINOMA OF CERVIX

Grouped according to League of Nations Classification of Extent of Disease

Stage	Number	Living	Per cent living 5 years
I	77	35	45.4
II	131	33	25.2
III	118	14	11.9
IV	17	0	0
Total	343	82	24.2

Table VII shows that 49.4 per cent of the cases falling into the League of Nations Stage I were saved for at least 5 years. 25.2 per cent of the Stage II cases received 5 year cures. 11.9 per cent of the Stage III cases lived for 5 years after the first radium treatment. None of the Stage IV cases survived the 5 year period.

TABLE VIII—FIVE YEAR END-RESULTS IN PATIENTS TREATED FOR CARCINOMA OF CERVIX
Comparison between League of Nations and Schmitz Classifications

League of Nations Classification	Schmitz	Number	Living	Per cent living 5 years
I	I & II	7	35	45.4
II & III	III	240	47	19.6
IV	IV	17	0	0

TABLE IX—FIVE YEAR END-RESULTS IN CARCINOMA OF CERVIX TREATED BY UNIFORM WOMAN'S HOSPITAL RADIUM TECHNIQUE

Does not include patients with previous or subsequent treatment or operation elsewhere or patients treated previous to May 1920 when method was unstandardized

	Number treated	Living	Per cent living 5 years
Total	255	61	24.3
Classes I and II Schmitz Stage I L.N. Limited to cervix	46	24	52.2
Classes III & IV Schmitz Stages III, III, IV L.N. Extended beyond cervix	209	37	17.7

Hospital technique 18.2 per cent of the Class III and IV Schmitz (League of Nations Stages II, III and IV), the inoperable patients were saved for 5 years or more.

TABLE X—FINAL SUMMARY OF FIVE YEAR END-RESULTS IN PATIENTS WITH CARCINOMA OF CERVIX

	Living	Per cent living 5 years
Total seen	357	23.8 "absolute cure"
Total treated	343	24.8 "relative cure"

Eleven cases were lost to the follow-up and have been recorded as dead of cause.
Completed follow-up—97.9 per cent

TABLE XI—CARCINOMA OF CERVIX UTERI TREATED BY WOMAN'S HOSPITAL TECHNIQUE MAY 1920—MAY 15, 1927 GROUPED ACCORDING TO CELL TYPE

	Number	Per cent of total
Total treated	262	100.0
Squamous I	55	22.1
Squamous I and II	25	9.5
Squamous II	0	0.0
Squamous II and III	10	3.8
Squamous III	24	9.2
Squamous I and III	10	3.8
Adenocarcinoma	22	8.4
Adenocarcinoma and squamous II	1	0.4
Unclassified	33	12.6

An attempt has been made as seen in Table XI, to group the cases of carcinoma of the cervix according to the type of cancer cell found on microscopical examination. In this series 91 per cent were epidermoid or squamous cell type.

TABLE XII—FIVE YEAR END RESULTS IN CARCINOMA OF THE CERVIX UTERI TREATED BY THE WOMAN'S HOSPITAL TECHNIQUE MAY 1920—MAY 15 1927 GROUPED ACCORDING TO CELL TYPE

	Number	Living	Per cent living 5 years
Total treated	262	65	24.8
Squamous I	55	17	20.3
Squamous I and II	25	3	12.0

general belief that adenocarcinomata of the cervix are more difficult to cure than the squamous cell carcinomata. The next best cure rate was 34.3 per cent for the squamous II type, and thirdly came the squamous I type with a 5 year cure rate of 29.3 per cent. Only 3 of the 24 patients, or 12.5 per cent of those showing squamous III cells survived for 5 years. It is interesting to note the exceptionally low cure rates for those cases which showed a combination of two types of cells. Only 12 per cent of the squamous I and II, none of the squamous II and III, and none of the squamous I and III types lived for 5 years. The 5 year cure rate for the unclassified group was 26.4 per cent. This is approximately what one would expect since it is almost the same percentage as the rate of cure for all cases.

Cure rate for all cases. 24.8 per cent
Cure rate for unclassified group 26.4 per cent

There were 33 cases in the unclassified group out of which 9 lived for 5 years or more. In 3 of these 9 cases the specimen obtained was too small to examine. One specimen was lost, 2 specimens were so atypical that no diagnosis could be rendered and in 3 cases no biopsies were taken.

Table XIII was made in an attempt to show the relation of cell type extent of disease, and its bearing upon prognosis. While the groups are very small and general statements are hard to substantiate, nevertheless it can be said that the more extensive the disease and the more malig-

nant and radioresistant the cell type, the worse the prognosis. Adenocarcinoma of the cervix, in this series, gave the best results and therefore the best prognosis. Of the squamous cell carcinomata the squamous II type affords the best prognosis, squamous I affords the next best prognosis, and squamous III gives the worst prognosis. Also, one sees that the further advanced the lesion has extended the worse the prognosis. Class I and II have a considerably better prognosis than Class II and IV.

SUMMARY

During thirteen years at the Woman's Hospital we have demonstrated that in a gynecological clinic with approximately 280 milligrams of radium element, nearly 25 per cent of those treated for carcinoma of the cervix can be saved for a period of 5 years or longer.

We believe that careful preparation and after care of these patients, with a meticulous personal follow-up clinic, and the employment of re-radiations for early manifestations of recurrence in the vaginal tract will materially increase the percentage of patients salvaged for five years.

A 50 per cent or better absolute cure rate with no radium mortality should be attainable in patients with the disease in its early stages.

FIVE YEAR "CURES" IN CANCER OF THE BREAST

BURTON J LEE, M.D. F.A.C.S., New York

THE object of this meeting is to present to the medical profession and the public, concrete facts dealing with the cures of patients who have been treated for various forms of cancer. It is highly desirable that we, as medical men, should stress the optimistic side of the cancer problem. The public at large, and many doctors, apparently believe that no case of cancer is ever cured. With such a pessimistic attitude of mind nothing can be achieved in any field of human endeavor, and there is no affliction to which mankind is subject where pessimism is more disastrous or optimism more useful, than in cancer. I feel that it is unfortunate that cancer has been referred to as the great scourge for it is just as respectable a disease as any other disease with which I am familiar and many patients treated correctly are cured of their ills permanently.

I have been asked to present to you a brief statement concerning the absolute number of 5 year cures at The Memorial Hospital for Cancer and Allied Diseases in patients treated for cancer of the breast by radical surgery, combined with pre-operative and postoperative irradiation. I have been told that percentage figures are not desired but that the absolute number of 5 year cancer cures in my own experience should be given. I have under personal supervision at the present time 90 patients who were operated on for cancer of the breast 5 or

more years ago. In all of these patients histological verification of the diagnosis of cancer was obtained and today they are entirely free from disease and constitute healthy, useful happy members of the society in which they find themselves. Several patients whom I have followed for still longer periods see me annually for a follow up visit always terming this yearly call our 'anniversary'.

I feel certain that this group of 90 women is as useful and happy as any other 90 individuals you can meet in perfect health. But how has this been accomplished? These women came for treatment at an early stage of the disease when one could reasonably hope for a complete cure of their ailment by a combination of surgery and irradiation.

The main reason why all of us do not have still larger numbers of these 5 year cured patients is because many women will persist in not consulting a doctor at frequent intervals, and will not adopt the plan of a careful complete physical examination by their doctor every 6 months. Moreover they will not seek the advice of a physician the moment any abnormal symptom referable to the breast appears. The other equally potent reason why more women are not permitted to enjoy this same state of a 5 year cure is that not infrequently doctors in their lack of wisdom assure patients that painless lumps in the breast are of no importance and have no serious import.

CARCINOMA OF THE BREAST

SURGICAL TREATMENT AND RESULTS FIVE, TEN AND FIFTEEN YEARS AFTER RADICAL AMPUTATION

STUART W. HARRINGTON, M.D., F.A.C.S., ROCHESTER, MINNESOTA

Division: Surgery The Mayo Clinic

THE surgical treatment of carcinoma of the mammary gland is based on the hypothesis that malignancy is localized at the onset and later in the course of the disease involves other tissues by way of the lymph, and occasionally the blood stream. If this conception of the disease is correct, it is manifest that the most important considerations in treatment are early recognition and immediate complete removal of the growth. The most important factors which influence the results of surgical treatment are the extent of the involvement at the time of operation, the thoroughness with which radical operation is done, and the degree of malignancy as shown by microscopic examination. The following surgical statistics and results of operation are based on a series of 237 cases in which operation was performed between 1910 and 1917 inclusive; this permits the compilation of results over a period of 5 years in all cases.

Recognition of malignant disease of the breast by clinical signs and symptoms depends on the duration of the lesion at the time of examination; these signs and symptoms are hopelessly inadequate in determining early malignant disease. If sufficient time is permitted to elapse, it is probable that 100 per cent of these conditions could be diagnosed clinically, but meanwhile much valuable time has been lost before treatment is instituted, and in most instances the patient will have lost any possibility of obtaining permanent cure from surgical treatment.

Fixation of the skin over the tumor is the most characteristic clinical sign of malignant disease; it was noted in 82 per cent of cases. In studying this group with reference to the presence or absence of lymphatic involvement, it was found that in 72 per cent there was metastasis to the regional lymph nodes, which indicates that if fixation of the skin has occurred metastasis will have occurred in approximately three fourths of the cases.

Malignant growths are rarely painful in the early stages of the disease, which is one of the chief reasons why patients with malignant disease in all stations of life, delay examination. In many instances they do not come for treatment until the lesion has ulcerated, as was shown in 7.9 per

cent of cases of ulcerated lesions operated on in 1930. This high percentage of cases in which an ulcerating lesion was present at the time of operation again emphasizes the fact that the patients are being seen late in the course of the disease, and also emphasizes the necessity of more earnest educational propaganda.

I do not believe that the presence or absence of metastasis to lymph nodes can be definitely ascertained on clinical examination in all cases. In the cases observed in the last year palpable nodes were found in 60 per cent and in 68 per cent of this 60 per cent definite axillary metastasis was found at the time of operation. In the remaining cases the enlarged nodes were found to be inflammatory. In the 40 per cent of cases in which enlargement of axillary nodes was not palpable, axillary metastasis was found in 39 per cent. In most cases these enlarged nodes were under the pectoral muscles along the axillary vein. In view of the frequency with which these palpable nodes are found to be inflammatory on microscopic examination I do not believe it is justifiable to refuse operation. In a review of cases of malignant tumor of the breast encountered from 1910 to 1930 I have tabulated the percentage of cases in which there was nodal involvement at the time of operation. It was found that the average percentage of patients who had nodal involvement in this entire period was 64.2 and that the percentage was little different among cases encountered in the last 10 years. In 1930 the percentage was 62.4. This again indicates that cases are being seen too late in the course of the disease to expect the best results from surgical treatment.

From a surgical standpoint, the cases of lesion of the breast which require most careful consideration are those in which a definite diagnosis cannot be made clinically and in which the question arises of whether it is best to keep the patient under observation or to treat the condition surgically. In all cases in which there is a single localized tumor without definite clinical signs of malignant disease, the only safe way to establish a definite diagnosis is by surgical removal of the tumor for microscopic examination. The tumor should be removed by wide excision, well away

from the limits of the growth and without trauma to the lesion. Usually I prefer to remove a wedge-shaped piece of tissue including the tumor. Microscopic examination of the tumor should be made immediately after its removal before the wound is closed. If the tumor proves to be malignant the operation should be completed as a radical amputation.

I do not believe that it is ever justifiable to remove any growth from the breast without immediate microscopic examination of frozen sections of the tissue and the manner of completing the operation is indicated by examination of the tissue. The poorest surgical results in carcinoma of the breast are obtained from secondary radical amputation after primary partial removal of the tumor. In a review of the series mentioned I found that 11 per cent of the patients had undergone a primary minor operative procedure and in these cases I performed secondary radical amputation. In this group lymphatic involvement had occurred in 79 per cent of cases as compared with 64 per cent of cases in which primary radical operation had been performed. The results of radical secondary amputation are correspondingly less satisfactory than after primary radical amputation. These cases in which a primary minor operation had been done do not give a correct impression of the results because in approximately 50 per cent of them operation could not be done; the condition was hopelessly inoperable at the time the patients presented themselves at the clinic. This is particularly true when some type of escharotic paste had been used on the breast primarily for in more than 80 per cent of these the condition is inoperable.

The best surgical results are obtained by primary radical amputation. In this series of 257 cases in which operation was performed between 1910 and 1936 the cases were divided into groups depending on whether there was nodal involvement. In the series without nodal involvement, 71.2 per cent of the patients are living 5 years after operation, 52.9 per cent are living 10 years, and 40.7 per cent 15 years after operation. In the cases in which there is involvement of nodes the results are not as satisfactory but probably are more favorable than when there is metastatic malignancy from growths elsewhere in the body. In the group of patients with nodal involvement, 26.3 per cent are living 5 years after operation, 14.6 per cent 10 years after operation and 10.5 per cent 15 years.

The technique of the radical operative procedure has been fairly well standardized. I do not make a uniform type of incision in the skin, for I

believe that the best results are obtained when the incision is planned in each case so as to remove the greatest amount of skin over the diseased portion and leave the least deformity and restriction of motion of the arm. If the incision is properly planned in accordance with the situation of the tumor sufficient skin can be removed so that there is little danger of local recurrence and skin grafting is rarely necessary except in the most extensive cases. In a general way if the tumor is in the upper or lower quadrant of the breast a vertical incision will give the best results in completely removing the growth and in giving adequate exposure for deep dissection. If the growth is in the extreme inner or outer quadrant of the breast a transverse incision is usually best. After the cutaneous incisions have been outlined dissection of the subcutaneous tissue is made around the entire operative field, the median portion of the dissection being carried to the median line of the body, the lateral portion to the border of the latissimus dorsi muscle extending below over the upper portion of the rectus fascia and above to the clavicle. Approximately two-thirds of the clavicular portion of the pectoralis major muscle is then divided and its attachment severed from the humerus. The lymph nodes along the upper portion of the brachial vessels are then thoroughly removed and the dissection is carried to the lower border of the pectoralis minor muscle. The attachment of this muscle to the coracoid process of the scapula is then severed. The dissection of the axillary and sternal lymph nodes is entirely completed; all of the nodes that lie along the lateral thoracic wall and in the axilla being removed, both above and below the axillary vessels, to the point where the axillary becomes the subclavian vein. The branches of the axillary vessels are caught and ligated as the dissection of the lymph nodes proceeds toward the sternum, the long thoracic and subscapular nerves being preserved. This completely outlines the tissues to be removed which are still attached to the thoracic wall, and which consist of the breast, the subcutaneous tissue, the axillary nodes and node-bearing fascia, the pectoralis minor muscle and the greater portion of the pectoralis major muscle. These structures are then dissected from the thoracic wall starting from the lateral aspect, ligating the perforating intercostal vessels. The anterior sheath of the rectus muscle is removed as the dissection proceeds toward the median line and all the carcinoma bearing tissue is removed in one mass.

The results of radical operation depend to a great extent, on the thoroughness with which the

TABLE I—RADICAL AMPUTATION FOR
CARCINOMA OF THE BREAST

(5 and 10 Year Results According to the Grade of Malignancy in 1,911 Cases in Which Operation Was Performed from 1910 to 1917 Inclusive)

Grade of malignancy	Cases	Per cent of total cases	Patients living, per cent of cases in grade	
			5 Years	years
Involvement of lymph nodes				
		7.6	0	0
		9		25
3	130	14.5	10.0	3
	871	20.0	0	3

		20.5	33	23.6
Total	111	10.7	66.4	44

operative procedure is performed. I do not think the importance of this can be overestimated inasmuch as the only possibility of obtaining cure from surgical treatment is from the original operative procedure. It has been my experience that secondary operative procedures have been of little benefit.

In cases in which a definite clinical diagnosis of malignant disease can be made the condition usually is fairly well advanced and the decision as to the type of treatment to be instituted depends on the amount of involvement present. In cases in which the lesion is unilateral, and clinical examination does not reveal evidence of distant metastasis primary radical amputation should be performed. In certain cases in which the supraclavicular nodes are palpable, radical amputation may be performed because of the possibility that the nodes are inflammatory. In such cases it is best to apply radium to the nodes subsequent to operation because of the possibility that they may harbor metastatic growths. I do not believe that operation is advisable if clinical examination demonstrates definite distant metastasis to the lungs, bones or liver. If there is an extensive ulcerating lesion and a possibility of removing the ulcerated portion and closing the skin, I believe radical amputation should be performed rather than a more palliative procedure such as a simple amputation. There is very little addi-

tional risk in radical amputation as compared with simple amputation and in cases of the kind mentioned, radical operation is in reality palliative. I believe that the prognosis is much better when radical operation is performed.

The most valuable indications as to prognosis in cases of carcinoma of the breast are obtained by study of the grade of malignancy present and by determining the extent of the disease as indicated by the absence or presence of lymphatic involvement. We are now making a study of the grades of malignancy in all cases of carcinoma of the breast in which operation has been performed since 1910. This study has not been completed, but the results are known in 1,911 of the cases in which operation was performed from 1910 to 1917 inclusive and this I believe is a sufficient number to permit a preliminary report. The results of this study are uniform throughout in that the results of operation in the presence of lower grades of malignancy were much better than in the presence of higher grades, and the results in cases in which nodal involvement was absent were uniformly better in all grades than in cases in which nodal involvement was present. The results of this study are shown in Table I.

The results in those cases in which postoperative roentgen treatment had been given and those in which it had not been given were compared. In the cases in which there was lymphatic involvement and roentgen treatment had been given the average proportion of patients with lesions graded 3 or 4 who were living after 3 and 5 years, was 4.8 per cent more than among a similar group who had not had roentgen treatment, and the average proportion of patients with lesions graded 2 or 3 or 4, who were living after 10 years, was 4.2 per cent less than among a similar group who had not had roentgen treatment. The proportion of patients living after 3 or 5 years, whose lesions were graded 1 or 2 was 2 per cent less than in a similar group who had had roentgen treatment. These results indicate that postoperative roentgen treatment may be of benefit for highly malignant lesions, particularly if there is lymphatic involvement, but it should not be used as a routine measure since the results are less satisfactory when it is used for lesions of lower grades of malignancy, and if the results after 10 years are considered, they appear to be less satisfactory when lesions are of the higher grades of malignancy. I believe that roentgen treatment is of benefit in selected cases but in certain other cases it may be detrimental. If severe reaction follows, its use should be discontinued. I have seen a number of cases of this

type in which distant metastasis occurred earlier than would have been expected from the degree and extent of the malignancy found at the time of operation. Because of lack of uniformity of results in treating the different grades of malignancy and because there was no marked variation in the results obtained whether or not roentgen rays were used I believe the practical importance of this study is that patients who are accepted for surgical treatment should have as radical and thorough an operative procedure as possible, since roentgen rays cannot be depended on to remove any malignant tissue that may be left as a result of incomplete operation.

CONCLUSIONS

1. Present clinical methods are inadequate to detect malignancy until it is fairly well advanced.
2. Microscopic examination should be made in all doubtful cases and this should be followed immediately by radical operation if the lesion proves to be malignant.
3. The best surgical results are obtained from primary radical amputation in cases in which there is no involvement of lymph nodes. In cases of this type reviewed 71.2 per cent of patients

were living 5 years after operation, 52.9 per cent were living 10 years after operation and 40.7 per cent were living 15 years after operation. In the cases in which there is involvement of lymph nodes the results are not as satisfactory but probably more favorable than those obtained when there are metastatic growths elsewhere in the body. In cases of this type reviewed 26.3 per cent of patients were living 5 years after operation, 14.6 per cent were living 10 years after operation and 10.5 per cent were living 15 years after operation.

4. The surgical results are not as satisfactory in cases in which secondary radical amputation is done following a previous primary partial operative procedure.

5. The most important indications as to prognosis were the degree of malignancy and the presence or absence of involvement of nodes.

6. Surgical results are more satisfactory in the presence of lower grades of malignancy.

7. Postoperative roentgen therapy is not a definite auxiliary to surgical treatment. In selected cases in which the grade of malignancy is high it may be of value but it is of no benefit if the grade of malignancy is low.

PROGNOSIS IN GASTRIC CARCINOMA TREATED BY RESECTION

GATEWOOD M.D. F.A.C.S., CHICAGO

From the Department of Surgery, Presbyterian Hospital of Chicago, and Rush Medical College, University of Chicago

ANALYZING the histories of all of the cases of carcinoma of the stomach entering the Presbyterian Hospital between January 1 1920 and December 31 1929 (1) I found that, where sufficient data were obtainable, the patients waited an average of 5.3 months before seeing a doctor and that a further delay of 8.3 months occurred before these patients came to

operation! The reasons for the delays are numerous, the most common being the fact that the patient had had some previous stomach trouble. However, lack of careful examination of the patient was very often a cause and the responsibility rested squarely with the physician. A third, which was present all too frequently was the fact that many physicians still feel that the patient

is hopelessly doomed from the start and that operative interference carries a high mortality with little or no relief.

On account of such notions in the minds of many physicians and patients, it has been deemed worth while to report those cases of proved carcinoma which have survived longer than 5 years. During the 10-year period 417 cases were discharged with the diagnosis of carcinoma of the stomach. Almost exactly one half or 208, of these were either inoperable at the time they were seen or refused operation. While it must be admitted that some of these patients had very few symptoms before they were considered inoperable,

the majority of them were the victims of procrastination. According to most postmortem statistics (2), three-fifths of gastric cancers occur at or near the pylorus and should give symptoms relatively early. Only about one fifth are in the cardiac portion and beyond the range of operability from the outset. Of the 209 cases which were operated upon, 30 per cent were found to be so extensive that the operation was purely exploratory. Fifty-eight resections were done. The operative mortality has been materially reduced in the last few years by more careful preparation of the patients and while it still seems high (about 18 per cent) it is only a trifle higher than for gastro-enteros-

tomy in cancer cases. The operation of choice has been wide resection of the mass together with all adjacent glands followed by Billroth II closure, or some modification of it such as the Polya or Balfour.

Of those patients who survived operation, 46.1 per cent lived over 3 years and 39.5 per cent have survived over 5 years, 1 patient being alive and well at the end of 12 years. In addition to this group 2 other patients have been observed during this period who were operated upon in 1915 surviving 16 and 17 years. Although a 5 year survival is by no means a criterion of a cure and recurrence may occur even after 15 years, the amount of relief and comfort to these patients has been enormous, especially when compared to the hopeless picture of medical management or the palliative operation of gastro-enterostomy. Following are brief abstracts of the histories of the patients operated upon prior to 1918 who have survived at least 5 years.

CONCLUSIONS

The terrific mortality from carcinoma of the stomach can be lowered by more careful work on the part of medical men and by judicious propaganda.

Seventeen cases of gastric carcinoma surviving the five-year period are recorded.

Wide resection carries very little more mortality than palliative operations and in this series, 40 per cent of the patients who recovered from operation have survived more than 5 years (100 per cent follow up).

Barring the discovery of some real cancer cure, our efforts must be directed to earlier diagnosis and prompt radical resection which will improve very greatly the outlook in this all too common carcinoma.

MALIGNANT TUMORS OF THE KIDNEY AND PELVIS OF THE KIDNEY

FIVE YEAR CURES FOLLOWING NEPHRECTOMY WITH PARTIAL OR COMPLETE URETERECTOMY

WALTMAN WALTERS, M.D. F.A.C.S., ROCHESTER, MINNESOTA

Division of Surgery The Mayo Clinic

FOLLOWING surgical removal of malignant tumors of the kidney at The Mayo Clinic from 1901 to January, 1927 110 patients have lived for 5 or more years. Inasmuch as malignant renal tumors were removed from 256 patients during this period there have been cures for 5 years or more in approximately 43 per cent (42.99) of these cases. Of further interest is the fact that 68 of the 110 patients have lived from 5 to 10 years 22 have lived 10 years or more, 15 have lived from 15 to 20 years and 5 have lived more than 20 years (Table I). Although the purpose of this paper is primarily to report the number of patients surviving longer than 5 years after the removal of malignant tumors the fact must not be lost sight of that among those patients who lived less than 5 years the surgical treatment directed toward the eradication of the disease undoubtedly prolonged the patients' lives and made life more comfortable.

In 41 additional cases the malignant tumor of the kidney was so extensive as determined by incision and exploration of the tumor that the lesion could not be removed and after specimens were taken from the tumor for microscopic examination, roentgen rays and radium treatment was instituted. Seven (17 per cent) of these 41 patients who had inoperable malignant renal tumors lived for more than 5 years (Table II). This group of 41 inoperable cases might well serve as a control group in evaluating the benefits of surgical removal of malignant renal tumors, and emphasis might be placed on the fact that in the group of operable cases in which the tumors were removed the percentage of 5 year cures was 43 whereas among those cases in which the lesion could not be removed surgically because of its extent, even though the tumor was treated extensively by roentgen rays and radium only 17 per cent of the patients lived more than 5 years subsequent to the beginning of such treatment. I should like, however, to give full credit to the apparent benefits of postoperative use of roentgen rays and radium applied over the former site of the malignant lesion as an adjunct to surgical treatment of these lesions. For many years, it has been a routine to give courses of roentgen

rays and radium immediately following recovery of patients from removal of malignant renal tumors, and in the group of 110 cases of 5 year cures, postoperative application of either roentgen rays or radium has been carried out in 33 cases. Roentgen therapy has been of further value in some cases in which highly malignant tumors appeared to have undergone fixation and therefore to be inoperable, in some cases that is after a course of roentgen therapy, the tumor decreased in size and became more mobile, enabling nephrectomy with removal of the tumor, to be accomplished successfully.

PATIENTS LIVING

It would seem that following removal of malignant tumors, if recurrence does not take place within 5 years one can justly anticipate complete and permanent cure. However, in order to determine accurately whether such a conclusion might be accepted as fundamental I have followed the progress of the 110 patients mentioned, and have found that 76 of them are living and well, whereas 34 have died. Analysis of the 34 cases in which the patients have died would indicate that recurrence had taken place in 16 metastasis to various tissues as follows: to the bone in 4, to the lungs in 3 and to the brain in 3. Of the 41 cases which I have designated as inoperable in which treatment was by roentgen rays and radium, although 3 patients lived for 5 years, 2 for 18 years and 1 for 15 years only 1 of the entire series is living at the present time. This would further emphasize the value of surgical removal of malignant renal tumors and the importance of recognition of such a lesion in its removable stage.

LONGEVITY DEPENDING ON BRODERS INDEX OF MALIGNANCY

For the last 10 years the grading of malignant tumors has been routine at the clinic, and Broders index of malignancy has been used. In addition to the grading of the tumors removed during this period at the clinic, Broders and Hand have re-examined grossly and microscopically 193 malignant renal tumors removed between 1901 and 1923, and have graded them on the basis of degrees of cellular differentiation interpreting

TABLE I.—FIVE YEAR CURES IN 256 CASES OF MALIGNANT RENAL TUMORS NEPHRECTOMY WITH AND WITHOUT PARTIAL OR COMPLETE URETERECTOMY

their results in relation to prognosis. Quoting from their paper The grade of malignancy was found to be higher if patients were less than 40 years of age as the degree of malignancy increased the length of postoperative life decreased. An interesting relation exists between the grade of malignancy of the number of patients dead. Of the patients who have died many more are found among those who had higher grades of malignancy. A larger proportion of those patients living following nephrectomy for malignant renal tumors had carcinomas of lower rather than of higher grade of malignancy. Study of postoperative results in cases of carcinoma of the kidney based on the degree of cellular differentiation in the tumor represents a distinct advance in knowledge of this disease.

In a study of the grade of malignancy of the 110 malignant renal tumors removed from patients who lived 5 years or longer it is noted that grades 2 and 3 occurred most frequently and that in 43 cases the grade was 2 and in 31 cases it was 3. Next in order of frequency were tumors of grade 1, 13 cases. In only 4 cases were there 5 year cures among those in which tumors were of grade 4.

Of further interest are the facts that in the group of 110 cases in which there were 5 year cures, 70 per cent of the patients who had tumors of malignancy graded 1 are living at the present time, 67 per cent of those with tumors graded 2, 63 per cent of those with tumors graded 3 and none of those with tumors graded 4. This, further indicates the accuracy of the method of determining the degree of malignancy and the prognosis in cases of operable malignant renal tumor.

TYPES OF MALIGNANT RENAL TUMOR

Adenocarcinoma or hypernephroma constitute practically all the malignant tumors of the kidney with the exception of primary, squamous cell epithelioma of the pelvis of the kidney. The ratio of squamous cell epithelioma to adeno-

TABLE II.—INOPERABLE MALIGNANT RENAL TUMORS (41 CASES) EXPLORATION RADIUM OR ROENTGEN RAY TREATMENT

	Cases	Per cent
Lived 5 or more years	7	17
Lived 5 to 10 years	6	
Lived 15 years	1	
Living at present time	1	
Dead	6

From unknown cause	2	

carcinoma is variously estimated to be 1:11 and 1:14. In the series of 110 cases in which 5 year cures were obtained hypernephroma or carcinoma existed in 100 of the cases whereas epithelioma of the renal pelvis were present in 7 and sarcoma in 3.

Sarcoma of the kidney is relatively rare. In an unselected group of 225 cases of malignant tumors of the kidney in which operation was performed in the clinic, only 10 of the tumors were sarcoma, and in the series of 110 in which 5 year cures were obtained, cases of sarcoma numbered 3. The assumption that sarcoma of the kidney affects chiefly young adults has not been borne out in our experience. For example, 8 of the 10 patients with sarcoma of the kidney were adults, whereas the tumors in a series of 13 children with malignant tumors of the kidney were reported by the pathologist as adenocarcinoma, sarcoma and Wilms tumor.

SYMPTOMS OF RENAL MALIGNANT TUMORS

The symptoms of lumbar pain, presence of a tumor in the region of the kidney and hematuria occurred individually or collectively in practically all cases of malignant tumors of the kidney. In a group of 367 tumors of the renal cortex reported from the clinic by Judd and Hand, one of these three symptoms was present in 99 per cent of the cases. Hence early recognition of an abnormal condition of the kidney should not be difficult. That the significance of such symptoms, however occasionally passes unrecognized is evidenced by the fact that in 193 cases of malignant tumor of the kidney in which nephrectomy was performed, the average duration of symptoms before operation varied from 17 to 21½ months. This delay it would seem, should not have occurred.

It is probably unnecessary to emphasize the absolute necessity of cystoscopic examination of patients with hematuria. In the presence of a history of hematuria, the burden of proof that a malignant tumor is not present in the bladder or the kidney lies directly on the examining physician and the only accurate method of determin-

ing or eliminating the possibilities is by use of cystoscopic examination, and of the other refinements of urological diagnosis, such as intravenous urography or pyelography.

The fact that the duration of life and the com-

pleteness of cure are proportionate to the degree of malignancy and the size and extent of the malignant lesion of the kidney should serve as a plea for earlier diagnosis and earlier surgical treatment of this lesion.

CARCINOMA OF THE PROSTATE

HUGH H. YOUNG M.D. F.A.C.S. F.R.C.S.I. BALTIMORE, MARYLAND

From the James Buchanan Brady Urological Institute, Johns Hopkins Hospital, Baltimore

IN 1904 after a study of postmortem specimens I devised a radical operation for carcinoma of the prostate and on April 7, 1904, carried it out on the first patient. The technique of this operation was as follows: The prostate was exposed by the perineum, as in Young's conservative perineal prostatectomy, the tractor having been introduced through an incision in the membranous urethra. After exposure of the posterior surface of the prostate, the diagnosis was confirmed. The operator then proceeded to remove the entire prostate with its capsule and urethra, neck of bladder, lower half of trigone, seminal vesicles and ampullae of the vasa deferentia, thus excising in one block the entire carcinomatous area with a large margin of normal tissue. Closure was then effected by anastomosing the bladder to the membranous urethra.

This operation has now been carried out in my clinic in 40 cases. The total mortality has been about 6 per cent and there is one series of 18 cases with only one death. Had the operation been confined to cases in which the prognosis was good, both the mortality rate and the percentage of recurrences would have been greatly reduced.

At the request of Dr. Martin I have confined this report to those cases in which the operation was performed five years ago or longer. I find in this category 29 cases. We have made a careful study as to recurrences in 25 patients who left the hospital and beg leave to report as follows: Seven patients are living and well without recurrence or metastases. The duration since

operation has been 5 years in 3 cases, 7 years in 2 cases, 9 years in 1 case and 18 years in 1 case. Five patients have died without recurrence or metastases. These lived the following periods: 1 patient, 6 years; 2 patients, 7 years; 1 patient, 9 years; 1 patient, 13 years. There are therefore, 12 patients who passed the 5 year period or 48 per cent cured.

The early patients all had incontinence of urine when on their feet. I believe that this was due to interference with the blood and nerve supply of the external sphincter. I therefore changed the operation. By dissecting beneath the anterior pelvic fascia I found it possible to preserve these and since then a large percentage of the patients have had complete urinary control.

On account of the marked encapsulation of the prostate by its own capsule and two layers of pelvic fascia, which surround it, carcinoma of the prostate is confined within three fascial coverings and rarely penetrates them until late. As the disease progresses it generally travels upward into the region behind the bladder and in front of the two layers of fascia. Carcinoma of the prostate therefore, probably presents the best prognosis for a radical cure of any of the deep seated organs, this remarkable encapsulation, confining the disease to the limits of the prostate itself, being the finest safeguard against invasion of adjacent tissue and giving the surgeon a splendid opportunity for a radical cure with the operation here presented which shows 48 per cent of cures over 5 years.

MALIGNANT TUMORS OF THE BLADDER

A REVIEW OF 165 CASES IN WHICH THE PATIENTS LIVED FIVE YEARS OR MORE FOLLOWING VARIOUS SURGICAL PROCEDURES

VIRGIL S. COUNSELLER, M.D., F.A.C.S., WALTER M. WALTERS, M.D., F.A.C.S., ROCHESTER, MINNESOTA
Division of Surgery, The Mayo Clinic

THE results following various surgical procedures in the treatment of carcinoma of the urinary bladder although not excellent are nevertheless gratifying particularly when it is considered that the average patient with carcinoma of the bladder may not seek treatment until several weeks after the onset of the disease. The high degree of perfection attained by the urologist in diagnosing the type of lesion, its extent, situation and degree of malignancy is a distinct aid in determining the type and magnitude of the operation as well as in evaluating the end-results.

At The Mayo Clinic from 1910 to January 1927 600 malignant tumors of the bladder were treated by various surgical procedures, consisting of resection, excision, surgical diathermy combined with ligation and reimplantation of the ureter, transplantation of the ureters to the back with total cystectomy and treatment by radium. In this group of 600 patients, 165 (about 28 per cent) were cured for 5 years or more. One hundred three of the 165 patients have lived from 5 to 10 years, 43 have lived 10 years or more, 14 have lived from 15 to 20 years, and 5 have lived more than 20 years. Sixty seven (40.6 per cent) of the 165 patients had recurrences although 42 of the 67 are now living and free from symptoms referable to the bladder. The deaths of 19 of the 25 patients were the result of local recurrence or metastasis. One hundred sixteen (70 per cent) of the 165 patients are alive and free from symptoms.

The choice of operation for malignant lesions of the bladder is determined principally on their site, extent, and grade of malignancy. It is known that those situated at the base of the bladder are of a higher grade of malignancy and are of the infiltrating type, usually involving one or both ureters. Those situated in the lateral walls and dome are more amenable to surgical attack and are less malignant. The lesions in 110 (66.66 per cent) of our 165 cases were on the lateral walls and dome, whereas 55 (33.33 per cent) involved the base, trigone, urethra, and ureteral orifices.

Seventy-four of the patients were treated by resection or excision, and of this number 28 (approximately 38 per cent) had recurrences. Fifty patients lived from 5 to 10 years, 17 lived 10

years or more and 7 lived from 15 to 20 years. Resection and excision combined with other surgical procedures were used in treating 70 of the 165 patients, and of this number 33 (47.1 per cent) had recurrence. However 35 patients lived 5 to 10 years, 25 lived 10 years or more, 6 lived 15 to 20 years, and 4 lived more than 20 years.

Transvesical electrocoagulation (diathermy) was used in treating certain tumors of the bladder mostly of the infiltrating type confined to the base of the bladder and considered non-resectable. Seventeen of the 165 patients were treated by this method. There were 5 recurrences (29.3 per cent). Sixteen of the 17 patients lived from 5 to 10 years and 1 patient lived more than 10 years. Fifteen (88 per cent) of the 17 patients treated by electrocoagulation are living and are free from symptoms referable to the bladder. If it is considered that the cases were judged to be inoperable, the results indicate that the patients who lived less than 5 years, and who were treated by diathermy undoubtedly lived longer and in greater comfort because of this treatment. It should, therefore, be considered a very effective method of treating not only the more malignant inoperable lesions, but those more favorably situated and less malignant.

Not infrequently palliative cystostomy for extensive malignant lesions of the bladder with the subsequent application of radium is justified. Two patients with such lesions were so treated with surprisingly favorable results. One patient lived 5 years and the other is living more than 15 years.

Total cystectomy with transplantation of the ureters to the back was performed on 2 patients. There has been no recurrence and both patients are living, 1 more than 5 years and the other more than 10 years.

The grade of malignancy was studied in 151 of the 165 cases in which the patients are living 5 years or more. In 14 the malignancy was not graded. In 38 cases the malignancy was graded 1, in 67 it was graded 2, in 30 it was graded 3, and in 16 it was graded 4. It should be noted that 105 (63.63 per cent) of all the malignant tumors were of the less malignant type (grades 1 and 2). Only

9.69 per cent were graded 4. It is further of interest that in the group of 165 patients living 5 years or more 76 per cent who had malignant tumors graded 1, 67 per cent of those with tumors graded 2, 66 per cent of those with tumors graded 3 and 62 per cent of those with tumors graded 4 are living at the present time. The relative high percentage of 5 year cures of patients with tumors graded 3 and 4 is striking but serves to emphasize the importance of treating malignant lesions of the bladder which at first seem inoperable.

A study of the recurrence of tumors according to the grade of malignancy reveals a rather uniform percentage of recurrence of tumors of all grades. In 67 cases the patients survived 5 years or more but they had definite local recurrences. Of these 67 patients, 15 had recurrent growths graded 1, 12 of whom are living; 33 had recurrent growths, graded 2, 20 of whom are living; 11 had recurrent growths graded 3, 5 of whom are living; and 4 had recurrent growths graded 4, 1 of whom are living. Considering the entire recurring group, 42 patients (62 per cent) have lived from 5 to 10 years, 21 (31 per cent) have lived 10 years or more, 2 (3 per cent) have lived 15 to 20 years and 2 (3 per cent) have lived more than 20 years.

Postoperative recurrence or extension of the malignant growth takes place regardless of the method of removal usually in the form of implants, either before or after operation or by direct extension beyond the tissue removed or along the lymphatic structures. Since recurrent growths of all grades were noted rather uniformly, it would seem that recurrence would develop in a variable percentage of cases regardless of the degree of malignancy. Recurrence after radical excision or electrocoagulation of a growth of low malignancy

is not so likely to occur as it is following the same procedure for a growth graded 3 or 4.

For many years it has been a routine procedure at The Mayo Clinic (introduced by Crenshaw) to request such patients to return in 3 months for a check up on the condition of the bladder then again in 3 months, then in 6 months and then in 1 year. In this manner many recurrent growths are discovered before symptoms develop thereby making it possible greatly to improve the end results. Unfortunately some patients disregard the follow up note and fail to return until there is extensive local recurrence requiring secondary surgical procedures.

Of the 67 patients who had recurring lesions in the bladder, 36 (53.73 per cent) were treated by transurethral fulguration or by radium. Twenty-six patients (75 per cent) so treated are living and are free from symptoms. Twenty patients (29.85 per cent) of the 67 required secondary surgical procedures by the suprapubic route. Only 8 (4 per cent) are now alive. The condition of 5 patients who did not return for a check up was considered inoperable according to the symptoms as given in correspondence. Only 2 patients (4 per cent) are known to be living. From the correspondence of 6 patients of the group recurrence was considered doubtful all of this group are now alive and well for periods of 5 to 15 years after operation.

It is apparent, therefore, that if results of treatment of malignant tumors of the bladder are to be further improved, then there must be a rigid selection of the surgical procedure that should be applied, as determined by the situation, extent and grade of malignancy of the lesion, together with a rigid follow up system.

TUMORS OF THE TESTIS

FIVE YEAR CURES FOLLOWING RADICAL OPERATION

FRANK HINMAN A.B. M.D. F.A.C.S., SAN FRANCISCO, CALIFORNIA

THE following presentation is an attempt to ascertain the value, if any of radical surgery in tumors of the testis and, in order to compare results, certain important characteristics of these tumors with reference to surgical treatment should be recognized and these characteristics may be discussed under the three headings (1) pathological, (2) clinical, and (3) therapeutic.

Pathological characteristics. The exact pathological nature of testicular tumors remains uncertain. New-growth may arise from any type of cell present in the testis so that connective tissue epithelial and mixed type tumors are possible. What ever interpretation is made as to character and origin, it should be well understood that both pathologists and clinicians agree that for practical purposes all tumors are to be regarded as malignant. In the pathological differentiation of these different tumors there are two outstanding characteristics. In one group is a mixed tumor type of teratoma in which all three germ layers (epiblast, hypoblast, and mesoblast) may be more or less equally represented in a typical tridermal teratoma, or there may be a one-sided overgrowth, first, of the epiblast, forming squamous epithelioma, basal celled carcinoma, chorio-epithelioma or a neuro-epithelioid type tumor second of the hypoblast, forming the simpler papillary adenofibromata adenocarcinoma or cirrhotic carcinoma and, third of the mesoblast, forming cartilaginous, myomatous or mesenchondro-endotheliomatous tumors. According to Bell, hypoblastic overgrowth is the commonest and epiblastic least common. In the other group are the homogeneous monocellular type of tumors which, according to one view (Chevassu and Bell) arise from the adult cells of seminiferous tubules just as cancer develops from an uncontrolled proliferation of adult cells from other glandular structures but, according to Ewing, are a one-sided cancer overgrowth in a tumor primarily tridermal. Whatever view is adopted, the clinical distinction of a mixed tumor or teratoma from a homogeneous monocellular tumor or seminoma is of considerable importance. It seems fairly well established that the seminoma is radiosensitive but that the teratoma is radioresistant. Both are highly malignant and metastasize by preference through primary lymphatics. Sarcoma is now known to be a

very rare tumor of the testis, although in the past it was frequently reported and probably referred to the pure round-celled seminoma. The only pure sarcomata of the testis are those arising from a connective tissue framework of which lymphosarcomata are commonest. Fibrosarcoma may arise from testicular tunics. Other sarcoma-like areas of heterogeneous tumors are in all probability a mesoblastic overgrowth of the testicular tumor or a type of sarcomatous change to which Bell applies the term "carcino-sarcoma" occurring in a structure essentially carcinomatous. For practical purposes, therefore, the clinician can recognize a mixed tumor or teratoma, in which the rare chorio-epithelioma belongs, and the pure uncellular seminoma with which the questionable sarcoma can be satisfactorily grouped.

A marked pathological characteristic of both these two types of tumors is mode of metastasis. Teratoma tends to metastasize earlier by way of primary lymphatics than seminoma but either type may show early general metastases, particularly to the lungs and liver. The primary lymphatic chain of the testicle has been well established anatomically and is the so-called pre-aortic lymph zone (Fig. 1).

Clinical characteristics. The cases of testicular tumors can be divided into three definite clinical groups, according to the nature of the growth and the absence or presence of evidence of metastases as determined by abdominal palpation of glandular masses or the X-ray indication of lung or other invasion. Group 1: the seminoma with or without clinical evidence of metastasis; group 2: the teratoma with clinical evidence of metastasis; and group 3: teratoma without clinical evidence of metastasis. This grouping is of importance in the application of surgery.

Therapeutic characteristics. There are now three recognized procedures in the treatment of a testicular tumor: (1) simple castration, (2) radical operation with or without castration, and (3) radical operation in which the testicle and its primary lymph zone are removed. The fact that the seminoma type tumors are radiosensitive and the teratomata are not gives at once a basis for differentiation of tumors with reference to surgical treatment. Experience has also taught that if metastases are evident on clinical study neither

Fig. 1 The primary lymphatic chain of the testicle.

simple castration nor an attempted radical operation can be successful. This means that the clinical group 1 above should be treated by radiation either with or without castration, that group 2 is a hopeless group and can only be treated palliatively which until more is known about the effects of radiation, does not prohibit its trial in all these advanced cases and that group 3 are the only cases in which an attempt to perform a radical operation is ever indicated. It will be found that there will be a certain number of cases in which radical operation is attempted and in which there had been no clinical evidence of metastases but in which inoperable masses will be found. It is at once obvious that simple castration will cure only those cases in which the testicle has been removed before any metastases have occurred, that there will be a certain number of radical operations before metastases have occurred but that in those cases in which metastases have spread into the primary pre-aortic lymph zone their radical removal is the only hope of cure when radiation is absent.

The radical operation for teratoma testis The feasibility and ease of an anatomical dissection of the primary pre-aortic lymph zone of the testicle is now fully established. More than 100 cases of radical resection have been performed by American surgeons with only one surgical death from pneumonia 10 days after operation. This is sufficient proof that the operation itself is neither dangerous nor difficult. With these 100 are in-

Fig. 2 Line of incision.

cluded 20 cases which were found after retroperitoneal exposure to be inoperable, which means that a large number of other cases must have presented difficulties of gland resection from vena cava and aorta but in all of which no serious damage or surgical injury was done as there has been no case of hemorrhage or accidental death at the time of operation. The technical steps of the operation have been thoroughly described elsewhere¹ and are indicated in Figures 2, 3 and 4. The objection by those who have not done the operation that the whole gland area cannot be removed anyway and so why attempt it is answered by proof of cure by lymphatic resection of cases with lymph gland metastases. The completeness and thoroughness of the gland resection depends as much on courage, determination and conviction that the procedure is right as on skill. The experience of Hepler cited below indicates that the abdominal resection should be extended above the renal pedicle.

In order to evaluate the results obtained by this operation the cases of clinical group 3 teratoma without clinical evidence of metastasis, may be advantageously subdivided into subgroup A, cases which proved to be inoperable or with mistaken diagnosis and which, therefore, can be omitted from the consideration, subgroup B, cases in which the lymphatics removed at operation show no evidence microscopically of metastasis and subgroup C, cases in which microscopic evidence of metastasis is found in the lymphatics successfully removed. From what has been said, it is

Hinman, Frank. The radical operation for teratoma testis with the report of five cases. *Surg., Gynec. & Obst.*, 19, p. 2217, 495-503.
Hinman, Gibson, and Kutzmann. The radical operation for teratoma testis; An analysis of seventy-nine cases, ten of which are personal. *Ibid.*, 1923, xxviii, 499-511.

Fig. 3. A Exposure of cord B diathermy of cord with cauterizer C stripping back peritoneum.

obvious that all cases of teratoma in subgroup C could be cured only by radical surgery. It is still an open question whether in a case of pure seminoma with or without clinical evidence of metastases (clinical group 1) radical resection should be attempted or entire trust put in deep X ray therapy.

The cases which are analyzed have been gathered from four sources (1) personal cases of radical operation (2) cases of radical operation by other American surgeons, the majority of which have never been reported and the information regarding which has been obtained by letter (3)

cases of simple orchiectomy with or without radiation gathered from the same source and (4) authentic cases of 5 year cures of abdominal metastases by deep X ray reported to the California Cancer Commission.

Twelve personal cases. There are 9 personal cases which were successful (3 in Group A excluded) all but one of which (Case 4) had teratoma. In 3 cases (Cases 6, 8, and 9) no microscopic evidence of metastases was found in the gland tissues removed. One died within 11 months with

Two radical operations have been done since this paper was written. In one (Case 11a) no metastases were found in tissues removed, in the other (Thomas) numerous metastatic glands were removed.

Fig. 4. Completion of operation.

extensive metastases to lung liver and abdominal glands. The other 2 are alive Case 8 for 8 years and 9 months Case 9 for 2 years and 10 months. In 6 cases microscopic evidence of metastases in the gland tissues removed at operation was found. Three have died of carcinomatosis Case 1 within 9 months Case 4 18 months and Case 6, 11 months. Of the 3 cases living all were alive and well at last report, Case 2 14 years and 8 months, Case 3 2 months (when last heard from, September 20 1918) and Case 8 4 years and 10 months. This gives a cure in 2 cases in which metastases were removed surgically (namely Cases 2 and 5) and in one case in which no metastases were found or removed surgically

(Case 8). The facts relative to these 9 cases and the patients names are given in Table I.

Ninety-one cases of radical operation by other American surgeons. The information of this series of 91 cases was obtained by letter sent to all members of the American Urological Association and to a few general surgeons who it was known had done the operation or of whom this was learned from the answers of some of the urologists. These cases are analyzed in four subgroups (1) Twenty cases in which the operation was attempted but found impossible of completion subgroup A inoperable cases Table II. (2) Thirty three cases in which no microscopic evidence of metastasis was found in the lymphatic

Fig. 3. I. Exposure of cord. B. division of cord with cautery. C. stripping back peritoneum.

obvious that all cases of teratoma in subgroup C could be cured only by radical surgery. It is still an open question whether in a case of pure seminoma with or without clinical evidence of metastases (clinical group 1) radical resection should be attempted or entire trust put in deep X-ray therapy.

The cases which are analyzed have been gathered from four sources: (1) personal cases of radical operation; (2) cases of radical operation by other American surgeons, the majority of which have never been reported and the information regarding which has been obtained by letter; (3)

cases of simple orchidectomy with or without radiation gathered from the same source; and (4) authentic cases of 5 year cures of abdominal metastases by deep X-ray reported to the California Cancer Commission.

Twelve personal cases. There are 9 personal cases which were successful (3 in Group A excluded) all but one of which (Case 4) had teratoma.¹ In 3 cases (Cases 6, 8, and 9) no microscopic evidence of metastases was found in the gland tissues removed. One died within 11 months with

Two radical operations have been done since this paper was written. In one (Case 11a) no metastases were found in tissues removed, in the other (Case 11b) numerous metastatic glands were removed.

initial metastasis is the real factor back of the 11 cures. Thirteen or 50 per cent, are alive and well 4 years and longer.

In 41 of these 80 cases metastases to pre aortic lymph nodes were found, in 7 seminomata and 24 teratomata (type not stated in 10). There is the one surgical death of the whole series in this group 10 days after operation, of pneumonia. Twenty three of the 41 cases have since died of metastases the majority within 1 year, 17 are living 6 of these 5 years or more (2 seminomata, 1 not stated, 3, teratomata). If teratomata are really and always radioresistant, then these 3 cures are directly attributable to successful radical resection of the pre-aortic lymphatics.

The series of 100 cases is summarized in Table V. Of the 80 cases "successfully" operated upon 35 per cent are dead of metastases and 63.75 per cent are living of which 17 cases or 20.1 per cent are cured (alive and well 5 years or longer).

The results of orchidectomy with or without radiation. In answering the questions about radical

surgery submitted by letter to American urologists, the following facts relative to results following simple castration with or without pre-operative and postoperative radiation were obtained. About 258 cases are listed in Table VI which gives the source of the information and the results, which are summarized in Table VII. Of the approximate 258 cases, 118 are dead, 124 are living but only 17 for 5 years or longer, a cure of only about 6 per cent.

Five year cures of abdominal metastases by deep X ray. The Cancer Commission of the California State Medical Society has been actively at work for some time. Recently, two subcommittees sent out to all members of the Radiological Society and of the western branch of the American Urological Association the following question:

Have you seen 5 year cures following radiation treatment of abdominal lymph gland metastases in testicular tumors? Six radiologists replied in the affirmative listing more than 12 cases and 10 urologists said yes, listing 23 cases giving the very encouraging total of 35 cures by radiation of cases hopeless from a surgical standpoint. The radiological committee chairman and the urological committee chairman have very kindly given me the names of the doctors reporting these cases

and, in order that the record be one of fact and not one of shrewd inference, each one has been written for details regarding the cases observed by him. The result, summarized in Table VIII, is very disappointing showing a probably authentic cure in only 3 cases but these 3 cases prove that certain types of testicular tumor are very radiosensitive and that deep X ray therapy can cure some cases which are absolutely hopeless otherwise.

SUMMARY

It is illogical to compare on their face value the different series of cases mentioned. That is not the present purpose. Rather is it a desire to determine whether radical operation is ever a justifiable procedure. The results of the 80 radical operations have the advantage in comparison over those of simple orchidectomy of being a selected group—cases in which no clinical evidence of metastases could be found—and a fair comparison would be with a similar selected series treated by simple orchidectomy. The results as presented, however are summarized for comparison in Table IX, showing 17 cures in 80 cases of radical surgery with one operative death as against 17 cures in 258 cases of orchidectomy without an operative death. Indisputable evidence

T—teratoma, S—seminoma.

* Of 6 cases, 1 had radical operation and all the other 5 died within 1 year.

† Subgrouping not stated.

‡ My impression is that all the lymph nodes were probably involved, but repeated examination failed to reveal any involvement because of previous X-ray treatment.

§ Testicles removed together with skin of scrotum, adjoining skin of thigh and lower abdomen and accompanying lymphatics, cord and spermatic vessels up to the hilum of the kidney and down to the apex of the vas.

¶ Given X-ray previous to operation and pathologist unable to find evidence of malignancy in testis or glands after radical removal.

10. Ingber		8-27-32	"No record of such a case and none seen by associates, Rodabaugh and Kile"	

metastatic glands were removed surgically. It must be conceded that without radical surgery these patients must have died of metastases.

CONCLUSION

1. The radical operation for tumor of the testis is indicated in cases without clinical evidence of metastasis in which after orchiectomy the pathologist reports a mixed type tumor.

2. The surgical risk of the operation in the hands of American surgeons is about 1 per cent, a perfectly justifiable risk in view of the high morbidity following simple castration and X ray

3. The fact that at least 3 of 24 otherwise hopeless cases (24 teratomata with lymph metastases removed) have been cured by the radical operation proves its possibilities.

4. The fact that half of the cases (18 of 36) in which the pathologist could find no evidence of metastasis in the gland tissues removed are living (4 years or longer) indicates that radical surgery is preferable to simple castration even in these cases, and the surgeon should not feel that radical resection was unnecessary even though the pathologist tells him that he has removed no metastatic cancer.

Mrs. W., operated upon 3 years after the beginning of her symptoms on March 7, 1931 at the age of 70 years. Her tumor was described by the physician who referred her as follows "There is a large growth on the left lateral wall which shows two or three bleeding points, and a large area of ulcerated surface which is covered with a shaggy layer of fibrinous exudate. This tumor is hard and nodular and involves left ureter. It is undoubtedly malignant and absolutely inoperable with any hope of future comfort to patient. At operation I found a tumor "covering the left angle of the trigone and adjoining base, about 4 by 2 centimeters in size and raised about 5 millimeters." Glass tubes of radium emanation amounting to 633 millicurie hours were implanted and two capsules of silver screened emanation left in the bladder the radiation from which was estimated at 490 additional millicurie hours. No attention was paid to a small secondary papillary tumor in the urethra. A small specimen was taken and found to be carcinoma, many years later graded as II. Postoperative radium irritation lasted about 3 weeks and it was 8 weeks before the suprapubic wound was healed. Cystoscopy at various periods up to 3 years after operation showed no return of the tumor. When last heard from in 1931 at the age of 83 years, 10 years after operation patient was quite senile but had normal bladder function and no recurrence.

Since 1925 with the exception of an occasional resection, my bladder cancers have been treated by implantation of so called seeds of gold or platinum varying from 1 to 25 millicuries of radium emanation. In my records previous to 5 years ago I find 69 cases of bladder cancers proved microscopically. Forty seven were treated by radium emanation implantation and 17 (36 per cent) of these have survived 5 to 10 years (alive and well excepting one who died following a negative exploration of his abdomen by another surgeon). The remaining 22 treated by other—presumably curative—procedures show a 10 per cent 5 year survival.

SUMMARY

The cases cited illustrate the fact that cancer in this generation like tuberculosis in the preceding one, is becoming each year more and more a curable disease.

MALIGNANCY OF CEREBRAL TUMORS

WINCHELL McK CRAIG M.D., F.A.C.S., ROCHESTER, MINNESOTA

Section on Neurologic Surgery The Mayo Clinic

TUMORS of the central nervous system have been diagnosed more accurately and treated more effectively as the result of the methodical pathological analysis instigated by a small group of investigators who realized the necessity of classifying these tumors with regard to their relative malignancy.

This more careful analysis has amplified our knowledge of all tumors of the central nervous system, and particularly of tumors of the brain. These tumors produce definite symptoms which, however, may also be caused by other intracranial lesions, such as aneurisms, abscesses, subdural hematomata, traumatic cysts and inflammatory conditions such as arachnoiditis involving either the claterna cerebello-medullaris, the optic chiasm or the cerebral hemispheres.

The entire group of brain tumors consists of pituitary adenomata, meningeal fibrosarcomata, acoustic neuromata, congenital tumors such as craniopharyngeal pouch cysts and dermoids, metastatic tumors, granulomatous tumors of syphilitic or tuberculous origin, angioblastic tumors, and gliomata.

The gliomata arise from the substance of the brain; they comprise only 40 per cent of all intracranial tumors and were formerly considered incurable.

Within the last decade, these tumors have been analyzed pathologically and clinically by Bailey and Cushing, Penfield, Globus and Strauss, Roussy, Greenfield, Kernohan, and others, and due to their efforts, definite order has emerged from the chaotic condition which previously existed. Tumors of the glioma group are no longer considered as having all the same degree of malignancy or as giving all the same prognosis, and this of course influences the surgical attitude. The tumor can be classified at the time of operation, and if its removal is feasible the operation can be planned in one or more stages, as indicated by the condition of the patient.

All tumors, regardless of their cellular nature, vary in malignant potentialities, and we are all familiar with the grading from 1 to 4 of malignant tumors which is based on cellular differentiation and which proves of great assistance in deciding on a surgical program as well as indicating the probable postoperative longevity.

Brain tumors of the glioma group are malig-

nant in that they invade the surrounding structures and tend to recur but do not metastasize to other parts of the body. They have been analyzed clinically and pathologically in a manner similar to cancer elsewhere in the body. However, instead of attempting to grade their respective malignancy based on the amount of cellular differentiation, they have been classified and tabulated according to the predominating cellular structure. The cells arising from the primitive medullary epithelium take on the characteristics of different types of cells, as development progresses toward adult and mature glial structures. These transitional cells have been designated spongioblasts, medulloblasts, astroblasts, and astrocytes. Tumors composed predominantly of these cellular structures have been classified as spongioblastomata, medulloblastomata, astroblastomata, and astrocytomata. Other cells which may produce tumors are the oligodendrocytes and the ependymal cells.

Consequently the nomenclature of gliomata thus evolved consists of such descriptive terms as spongioblastoma multiforme and polar spongioblastoma, medulloblastoma, ependymoma, and so forth. For the purpose of convenience, I am using only 7 of these divisions to illustrate the relative malignancy of these tumors and the distinct clinical and surgical advantage of their classification. These groups are being constantly changed, new names being added and old names discarded, as analysis of the gliomatous tumors becomes more nearly universal and better understood.

The tumors which could be pathologically classified under spongioblastoma multiforme, medulloblastoma, oligodendroglioma, astroblastoma, astrocytoma, and ependymoma form the basis of this report, although there are other smaller groups into which some of the gliomata can be divided.

Of these, the spongioblastoma multiforme and the medulloblastoma rank as the most malignant and would compare favorably with a carcinoma graded 4 elsewhere in the body. The average periods of survival of patients who have these tumors has been given as 12 and 17 months, respectively, making the possibility of a 5 year cure very remote. Fortunately these two groups comprise only 42 per cent of the total group of gliomata. There is a distinct difference between these two

groups and the remaining divisions, because in all of the five remaining groups it has been possible to trace 5 year cures. The astroblastoma, the ependymoma, and the polar spongioblastoma can be grouped together with regard to their malignant potentialities, and would correspond to tumors elsewhere in the body of malignancy, graded 2. The astroblastomas represent 2 per cent of the gliomata, the polar spongioblastomata, 7 per cent and the ependymomata, 4 per cent, which gives a total of 11 per cent for this intermediate group. The average period of survival of patients who have such tumors is 28, 32, and 46 months, respectively.

The last combination of these pathological groups comprise the oligodendrogliomata and the astrocytomata, the cellular structure of which indicates malignancy of low grade, they would correspond in malignancy to carcinoma graded 1 elsewhere in the body. The astrocytomata comprise 27 per cent of the gliomata and the oligodendrogliomata 18 per cent in all 45 per cent this is a greater proportion than that of tumors corresponding to grade 4. The average period of survival of patients who have astrocytoma has been given as 66 months and of those who have oligodendroglioma as 76 months.

Thus, it is apparent that investigation has completely changed the clinical and surgical attitudes toward intracranial gliomata, inasmuch as they have been found to comprise only 40 per cent of intracranial neoplasms, and of this 40 per cent less than half fall into a group analogous to carcinoma graded 4 elsewhere in the body. About half the gliomata can be compared to tumors of malignancy graded 1 elsewhere in the body and about 11 per cent can be compared with tumors graded 2.

Operability and prognosis concerning gliomata depend not only on their cellular characteristics, but also on their situation within the brain, on the invasion of surrounding tissue and on the permanent injury which has resulted from pressure. In view of these facts, I have taken for analysis concerning 5 year cures only those patients who have remained relieved of symptoms over this period, and who have been able to return to work without any apparent aberration of function.

Five year cures followed total removal of tumors in all groups except those composed of spongioblastomata and medulloblastomata. In these two groups relief was only palliative and temporary. Five year cures resulted in the group composed of astroblastomata, following total removal of tumors at the primary operation, sub-

total removal followed by radiotherapy, and subtotal removal followed in 2 or more years by total removal at secondary operation. Five year cures resulted in the group composed of polar spongioblastomata following total removal of the tumor at the primary operation, total removal by means of three operative procedures at intervals of 2 years, subtotal removal followed by roentgen treatment, and removal of mural nodules in cystic tumors. Five year cures resulted in the group composed of ependymomata following total removal at the primary operation or in multiple stages, as well as subtotal removal with subsequent treatment by radium. Five year cures resulted in the group composed of oligodendrogliomata following total removal at the primary operation and subtotal removal in two or three operations separated by intervals of from 1 to 3 years, and 1 patient was well for 5 years following decompression and one treatment with radium. Five year cures resulted in the group composed of astrocytomata, from total removal at the primary operation, from total removal following three operations, and from subtotal removal followed by treatment by means of roentgen rays and radium.

A review of the 5 year cures emphasizes the fact that more careful pathological analysis has been invaluable in classifying the tumors of the glioma group with regard to their operability and response to irradiation. In dealing with the most malignant group, comprising the types known as spongioblastoma multiforme and medulloblastoma treatment can be only palliative even when apparent total removal is followed by radiotherapy.

Tumors of the remaining groups, which are less malignant, have responded to one or more surgical procedures and irradiation with resulting 5 year cures. It is rather difficult to estimate the value of treatment by radium and roentgen rays in treatment of these tumors at the present time, because in most of the cases in which 5 year cures occurred radiotherapy was given at some time during the period of treatment. Repeated operations on the less malignant types of glioma have been followed by 5 year cures so consistently that it has become the treatment of choice, depending of course on the condition of the patient and the amount of permanent injury which has been produced.

It is apparent, therefore, that gliomata comprise only 40 per cent of intracranial tumors, and are not all hopelessly malignant. It is true that the more malignant tumors can be treated only palliatively, by operation and irradiation,

but the classification and analysis of this group of tumors have emphasized the fact that some of the more benign types respond to treatment so successfully that complete relief of symptoms fol-

lows one or more operations, and tumors of the entire group are not only receiving more efficacious treatment as time goes on but more permanent cures are being realized.

LARYNGEAL CANCER

STATISTICAL REPORT ON FIVE YEAR CURES

FIELDING O. LEWIS, M.D. F.A.C.S., PHILADELPHIA, PENNSYLVANIA

LARYNGEAL cancer may be intrinsic or extrinsic. The surgical treatment (laryngofissure) in early intrinsic cancer of the larynx yields a more striking and lasting result than can be claimed in any other internal region of the body: the lymphatic arrangement is to a marked degree confined; metastasis is therefore, late. About 80 per cent cures is the reported results of experienced operators.

I have performed the operation of laryngofissure on 10 patients, with the following results:

The first patient, who died of recurrence, should have had a total laryngectomy. Four are free from any evidence of recurrence after more than 5 years: 1 11 years 8 months; 1 9 years 4 months; 1 3 years 7 months; 1 5 years and 2 months. The remaining 5 cases have not quite reached the 5 year period since operation, but are still free from recurrence.

Our records show that in the group of advanced

intrinsic cancer in which total laryngectomy was performed, there are 83 cases: 51, or about 63 per cent, are living and remain free from the disease. Of the 51 living cases, 33 have passed the 5 year cure period: the longest period being 11 years since the operation.

In extrinsic cancer of the larynx with varying degrees of cervical lymphatic metastasis, extension to the tongue, pyriform sinuses and oesophagus, which only a few years ago were considered hopeless are now promised a brighter future. In this group, we have operated upon 75 patients: 16, or slightly over 21 per cent, are living and enjoying life free from the disease beyond the 5 year period—the oldest in point of operation, being 11 years.

One patient with squamous cell carcinoma of the epiglottis is living and well after 7½ years following a subhyoid pharyngotomy. In all cases the diagnosis was confirmed by biopsy.

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 1. Early epithelioma of the right vocal cord. Note the infiltrating type of lesion with inflammation of the cord. In this type of case 80 per cent of cures may be expected by laryngofissure.

Fig. 2. Advanced bilateral intrinsic cancer of the larynx. In this type of case, total laryngectomy offers a large per-

centage of cures provided there is not a marked glandular metastasis.

Fig. 3. Extrinsic cancer of the larynx. Total laryngectomy with dissection of the cervical glands, plus irradiation, have given most encouraging results in treating this type of laryngeal cancer.

Fig. 4. Extrinsic carcinoma of the larynx. Laryngectomy and excision of the upper portion of the esophagus, November 1921. Patient still living with no evidence of recurrence.

Fig. 5. Advanced intrinsic carcinoma of the larynx. Total laryngectomy February 1922. Patient aged 34 years. No evidence of recurrence to date.

Fig. 4

Fig. 5

Fig. 6. Advanced intrinsic carcinoma of the larynx. Total laryngectomy July 1925. Still free from recurrence. Has a splendid buccal voice. At right, photograph of larynx removed from patient.

Fig. 7. Physician, aged 76 years. Advanced intrinsic carcinoma of the larynx. Total laryngectomy February 1926. Still free from recurrence. Continues in the practice of medicine. At right, photograph of larynx removed.

MALIGNANT TUMORS OF THE EYE

JONAS S. FRIEDENWALD, M.D., F.A.C.S., BALTIMORE, MARYLAND

From the Wilmer Ophthalmological Institute of the Johns Hopkins University and Hospital

MALIGNANT tumors of the eye form a very small fraction of the clinical material of a practicing ophthalmologist. While we have all seen cases of successful extirpation of malignant tumors of various types in this domain, the statistics of the surgical results obtained by any single operator or institution would be most inadequate for the purposes of this symposium. In answering your chairman's request therefore I appealed to Major P. E. McNabb, the curator of the Army Medical Museum for data available in the Division of Ophthalmic Pathology which is conducted under his direction and under the joint auspices of the three national associations of ophthalmologists. I am deeply indebted to Major McNabb for the data which are presented in tabular form below (Table I).

In reviewing these figures certain facts of interest may be mentioned. The high percentage of cures among cases of carcinoma of the lids and conjunctiva is not surprising. The majority of these belong to the group of basal cell carcinomas of low malignancy but of great local destructive power. Occurring in or near the eye they usually come to operation at an early stage.

More significant are the 50 per cent cures found among the retinoblastomata. It is to be noted that, in this group, there was recovery in all those cases in which the eye was removed before extrabulbar extension had taken place. It is in relation to this group of cases that an improved awareness of the benefits of surgical treatment and of early diagnosis could be most useful.

Perhaps the most surprising aspect of these figures is to be found in relation to the malignant

melanomata, tumors generally regarded as the most malignant of all malignant growths. Even more significant is the fact that of the 18 of these cases in which enucleation was performed before extrabulbar extension had occurred 11, or 61 per cent, survived for 5 years or more. Here again we have evidence of the importance of early diagnosis and treatment. Not all these can be counted as permanent cures, for it is well known that late development of metastatic growths, 5, 10, even 20 years, after the removal of the primary growth may occur in these cases. Perhaps it may be not inappropriate to ask the distinguished group of surgeons here assembled what they consider may be the possible factors which hold the metastatic growths in abeyance during these long periods, or what may be the factors which release their growth again in malignant development. If we knew the answers to these questions, we might be a great deal nearer to the control of this terrible disease.

TABLE I

Tumor	Number of cases	Number with local recurrence	Dead from metastasis or other causes	Dead from other causes	Living and well 5 years
Carcinoma of lid and conjunctiva Per cent	4	20	20	20	3 60
Retinoblastoma Per cent	2	25	42	7	7 30

SUMMARY OF SIXTY FIVE "CURES" OF CANCER ABOUT THE MOUTH

V. P. BLAIR M.D., F.A.C.S. ST. LOUIS, MISSOURI
From the Department of Surgery Washington University School of Medicine

IN responding to the request for a summary of our 5 year cures of true carcinoma of the mouth and contiguous tissues we have tabulated all traced cases of true cancer (basal cell excluded) treated by us between 1915 and 1928 which are known to have been alive and apparently free of recurrence more than $4\frac{1}{2}$ years after treatment of the primary growth. We have also attempted to convey some idea of the extent of the growths and with some hesitancy our interpretation of the cell differentiation.

Fifty five of the patients are from a series of cases reported previously and represent about 25 per cent of the total. In this series early growths were but 4.7 per cent, medium 16.6 per cent, advanced 55.5 per cent, 23.2 per cent were inoperable so that this 55 might be considered as 33.3 per cent of those originally presenting any possible chance of cure.

The relative discrepancy between the stage of advancement and the number of cures as shown in Column A of Table I is explained by the predominance of advanced cases in the series.

Over 65 per cent were classified as advanced or inoperable.

Column B Table I shows a more definite proportion between cell differentiation and cures and Column C shows a striking relation between 'cures' and lack of demonstrable gland involvement. However there are enough cases with undifferentiated gland metastases that have gone 5 years without recurrence to show that even this extent of growth may not be a hopeless condition.

Table II indicates the type of treatment, which by preference, was gross destruction of the primary area, followed by radical neck dissection in every case in which that was practicable.

Since 1928 our proportion of supposed cures from radiation has very definitely increased.

TABLE II—TREATMENT

Treatment	Cases
Radical operation primary growth	14

FIVE YEAR CURES IN CANCER OF THE MOUTH, LIP, NOSE ETC.

FERRIS SMITH, M.D. F.A.C.S., GRAND RAPIDS, MICHIGAN

THE cases presented represent well developed or extensive lesions in most instances previously treated with escharotics or radiation.

2 The early superficial basal cell lesions treated with radium are omitted.

3 Seven cases, not included in this report, with squamous cell lesions, lived beyond 5 years but died later of secondary lesions.

4 Our experience leads us to believe that radium has only occasional value in squamous cell lesions and that coagulation in association with mass removal of the involved area, produces the best result.

5 The prime purpose of management is elimination of the lesion. Restoration of function and appearance demand proper consideration.

CANCER OF THE SKIN

IRWIN P. ZEISLER AND CHICAGO

PRECANCEROUS LESIONS

IN this report an attempt will be made to present a statistical study of 500 unselected malignant new growths of the skin that were treated in private practice in the years 1914 to 1930 inclusive. Personal observation and a review of the literature lends support to the belief that cancer of the skin is not on the increase; that patients have become educated to apply for treatment earlier in the course of the disease and that more effective methods of prophylaxis and treatment are available. As long as the cause of cancer of the skin is not known, outside of the rôle of heredity and the congenital inherent tendency observed in that rare condition known as xeroderma pigmentosum it is important to recognize such factors as may produce long continued irritation as exciting causes. Among these are mechanical, chemical and actinic stimuli especially overexposure to wind and sunlight, occupational hazards in which arsenic, tar pitch, paraffin and radio-active substances act as carcinogenic factors, and finally the changes in the senile skin that predispose to malignancy. It is well known that an epithelioma seldom develops from a normal skin. The only effective preventive that we possess is a careful clinical, histological and morphological study of the so called precancerous dermatoses and their eradication. The more important precancerous lesions that demand attention are: (1) the senile keratosis which occur so frequently in elderly people on the exposed surfaces and which are known to develop into either basal or squamous types of epithelioma—seborrheic keratosis much less frequently undergo malignant degeneration; (2) leucoplakia with its associated etiological factors, tobacco and syphilis; (3) roentgen and radium keratosis and chronic radiodermatitis; (4) the scars of lupus vulgaris; and (5) certain nevi especially the black or blue-black pigmented moles and the hyperpigmented lentiginos of the aged from which may develop the most malignant type of cutaneous neoplasm the melanocarcinoma. Paget's disease and Bowen's disease were formerly considered to be precancerous but are now known to be cancers at their onset.

CLASSIFICATION OF EPITHELIOMATA

Prompt recognition of early lesions is as important in cancer of the skin as it is in cancer else-

where. A biopsy should be done if possible in all cases to determine the degree of malignancy and the probable radiosensitivity. The dangers of a biopsy have been overemphasized. By far the largest number of skin cancers about the face will be found to be of the basal cell type, also classified as non-epidermoid or rodent ulcers. The slow growth, low degree of malignancy, absence of metastases, and relative radiosensitivity gives a favorable prognosis in at least 90 to 95 per cent of these cases. Failures in our experience have occurred in less than 5 per cent and can be attributed to invasion of the deeper tissues such as periosteum, cartilage and bone to inadequate treatment or negligence on the part of the patient. Squamous cell, prickly cell or epidermoid cancers of the skin are much more dangerous, are characterized by rapid growth, early invasion of the deeper tissues, a tendency to early metastases and are more difficult to cure although Regaud has shown that the radiosensitivity is the same for both forms of skin cancer. Practically all cancers of the lip, buccal mucosa, floor of the mouth, tongue, and penis are of this type. In addition the carcinomata that develop on the site of a preceding radiodermatitis, in the scars of lupus vulgaris, and most of those of the extremities, belong in this group. An experienced dermatologist will as a rule have no difficulty in distinguishing a basal from a squamous lesion clinically but surprising variations in histological structure are often encountered when a biopsy is done. Another intermediate group the basal-squamous type has recently received careful study and it has been shown that lesions apparently of the basal type that metastasize belong in this group. Finally, there are a group of rare cases of multiple benign superficial epitheliomata, either basocellular or prickly cell or mixed, which can be differentiated histologically and clinically from Bowen's intra-epidermic carcinoma and the so called extramammary Paget's disease.

METHODS OF TREATMENT

Cancer of the skin on account of its accessibility and the readiness with which it can be recognized, lends itself peculiarly to successful treatment by surgery, chemical and electrical cauterization, and roentgen and radium therapy. In deciding on the best procedure to employ it is essential to consider the type of lesion, ex-

pecially its depth extent mobility and the anatomical location. The duration the histology probable radiosensitivity and the effect of previous treatment are also of importance. The underlying principle of all forms of treatment is the destruction or radical removal of the cancer cell. Surgical excision will cure permanently many selected cases of epithelioma but in certain locations such as the nose or eyelids may be impractical. Equally favorable statistics can be presented by the advocates of modern roentgen and radium therapy. In our own practice we have employed at various times all the recognized methods of treatment and have not relied on any one single procedure. It is only natural that in a 20 year period considerable variation in prevailing modes of treatment should have occurred. In basal cell lesions we prefer to do whenever possible a preliminary thorough curettage under local anesthesia followed by cauterization of the base with acid nitrate of mercury (liquor hydrargyri nitratis) after the well known method of Sherwell. This is invariably supplemented by intensive roentgen or radium therapy although in recent years we have relied mainly on the latter. The cosmetic results are excellent and we have encountered no complications even in deep seated lesions about the eyes or ears. When cartilage or bone is involved either surgery, cautery removal or electrocoagulation is advised rather than radiotherapy. In squamous cell epitheliomata, particularly early lesions of the lips face or extremities our preference has been for a preliminary destruction with the electrocautery followed by radium therapy. Patients in whom the glands were involved at the time of examination were not

treated and are not included in our series as it has been our principle to refer these patients for surgical treatment.

Whether prophylactic radiation or a surgical dissection of uninvolved glands is advisable as a preventive measure is a debatable question. It has also been our experience that all roentgen and lupus carcinomata should be treated surgically, or with the high frequency knife with subsequent plastic repair when necessary. Recurring cases of squamous carcinoma of the skin are treated with bipolar electrocoagulation or by interstitial platinum radium needles containing 1 or 2 milligrams of radium element inserted for 24 hours or longer. Suitable lesions of the tongue and buccal mucosa were formerly treated with gold radon seeds although we have records of several cases of cure with surgical diathermy without radium. At the present time we prefer the method of radium puncture used at the Curie institute enough 1 and 2 milligram needles being sutured in the tongue to give the necessary radiation dose in 7 days with due regard for the complications that may arise in the course of the treatment.

Radium therapy. The technique of radium therapy in skin epitheliomata will naturally vary

with the amount of radium at the disposal of the operator. For the majority of superficial lesions following curettage and cauterization, we have found that surface contact applications with lightly screened full strength flat glazed applicators to be sufficiently accurate and effective. For more deep seated and extensive cases, radiation is used at a distance of 1 centimeter with molds or blocks of tubes screened with 0.5 millimeter gold and 1.0 millimeter rubber (the dose being 50 to 60 millicurie hours per tube figured on the basis of approximately 1 tube for each square centimeter. The entire dose may be given in a single treatment or over a period of four successive days after Regaud's method. In the tumor clinic of the Michael Reese hospital at the present time the Curie technique is being carried out with excellent results. Individual molds of Columbia paste are prepared for each patient and 5 or 10 milligram tubes are attached on the outer surface of the mold permitting uniform and accurate radiation. This technique is especially suitable for lesions around the eyes and for lip cases.

Röntgen therapy. The technique of roentgen therapy in our hands has also changed. Up to

1920 we used the old method of fractional irradiation of Schiff and Freund, coils and gas tubes being used. Whereas this method was apparently fractional the actual result was to give an erythema dose within a short period, and therefore it was in effect an intensive treatment. Since 1920 we have used the standardized MacKee method of hyperintensive or massive dose radiation, 2 or 3 times the erythema dose being given in a single treatment or the dose being divided over several applications with a potential of 100,000 volts and no filter. The percentage of primary cures has not been markedly increased but there have been fewer recurrences and a decided saving of time. Roentgen therapy is of course also of great value as a postoperative treatment.

ANALYSIS OF CASES

Among the 500 malignant new-growths of the skin 356 were classified as basal cell epitheliomata, of which 320 were early superficial nodular or nodulo-ulcerative types and 36 were deep seated and infiltrating. Six cases were so far advanced when first seen that they were considered hopeless and were not treated or received only palliative treatment. Eight cases were classified as failures and eventually died of the disease and 30 recurrences were observed mostly during the first year all except 2 of which yielded to further treatment by cautery radiation or surgery. Three cases are known to have succumbed to late recurrences at an advanced age. Therefore, there were in these 356 cases 310 primary clinical cures (87 per cent) and 19 failures (6 per cent). If we include the recurring cases cured by further treatment the percentage of cures would be close to 94. However 58 cases did not remain under observation longer than 3 to 6 months and the percentage of 1 to 5 year cures therefore cannot be estimated as higher than 70 per cent. Many patients treated 15 or 20 years ago are known to have died of other causes and an attempt to follow up cases not heard from for years has been found to be unproductive of results. We have had great difficulty in having patients come in for observation at regular intervals for a 5 year period after

TABLE VIII—SARCOMATA AND MELANOMATA

	Clinical cures Cases (1 to 5 years)	Failures
Melanocarcinoma	7	0
Localized sarcomata	6	5
Sarcoma generalized metastatic	5	0
Kaposi's sarcoma	1	0

they have been clinically cured. Another important point to remember is the tendency in elderly patients to develop multiple successive epitheliomata in different locations. We have several patients followed for 5 to 20 years who belong in this group. For example an elderly woman of 61 was treated in 1913 for an extensive rodent ulcer of the temple which was cured and remained permanently well. During the next 20 years she was cured of at least a dozen basal lesions but eventually died at the age of 81 of a basal-squamous carcinoma of the cheek which recurred after treatment by surgical diathermy and radium and metastasized to the cervical glands. From the standpoint of a 5 year cure the lesion on the temple might have been considered a success but we have included these cases among the failures. Another woman of 77 was cured in 1914 of a large flat rodent ulcer of the forehead and a basal lesion of the inner canthus. Numerous epitheliomata were successfully treated in the next 14 years but she finally died at the age of 91 with a resistant squamous lesion of the cheek.

Of 102 squamous epitheliomata 74 were early superficial and 28 infiltrating and deep seated. Seven cases were so advanced that only palliative measures were advised. Twenty one involved the tongue and buccal mucosa with 14 failures. Of the remaining 81 cases including 34 lip cases there were 12 failures including recurring cases, of which 9 were fatal. The percentage of clinical cures was therefore about 71 and if we deduct 20 cases that were not followed the percentage of 1 to 5 year cures drops to 51. If we were to omit the intra-oral cases which had a mortality of 66 per cent the percentage of cures would be much higher. In this series of cases were 6 advanced cases of lupus carcinoma, 3 roentgen carcinomata, 3 carcinomata of the extremities that became metastatic and other cases which

TABLE IX—SUMMARY OF RESULTS OF TREATMENT IN FOUR HUNDRED AND SIXTY-ONE EPITHELIOMATA ALL TYPES

	Cases	Per cent
Basal cell epitheliomata	359	
Clinical cures, 1 to 5 years	252	70
Clinical cures not followed	58	16
Recurring cured by further treatment	30	8

Clinical cures not followed	20	10
Recurring cured by further treatment	3	3
Total clinical cures	72	71
Hopeless cases (no treatment or palliation)	7	
Failures (late recurrences, fatal cases)	23	29
Total	102	

had been ineffectually treated by surgery radiation pastes etc., and had become radioresistant.

We have had no cures in 7 cases of melanocarcinoma and have seen only disastrous results from surgery. It is our impression that these patients will live longer if they are left alone. The treatment of localized sarcomata by combined surgery and irradiation was successful in 5 cases.

CONCLUSIONS

In conclusion we feel that the treatment of cancer of the skin must be individualized, must be based on a thorough knowledge of the pre cancerous dermatoses and an expert appraisal of the clinical and histological features of each case. The therapeutic approach should aim to utilize all the known agents at our disposal including surgery, chemical and electrical cauterization radium and roentgen ray. In epitheliomata of the basal cell type the percentage of cures should reach close to 95 per cent. The prognosis in squamous lesions should be more guarded.

SYMPOSIUM TREATMENT OF FRACTURES

DEPRESSED FRACTURES OF THE SKULL

HOWARD C. NAFFZIGER, M.D., F.A.C.S., SAN FRANCISCO, CALIFORNIA

TREPHINING for depressed fractures is an operation of antiquity but only recently has there been an experimental basis to indicate the effects arising from long continued bony depressions. Although trephining was done in ancient Egypt, and even in earlier times, the notes made by Hippocrates are among our first records of the surgery of depressed fractures. He counselled against operation and gave the sound advice that fractures with depression were not particularly dangerous unless the membranes were ruptured. The opposite view favoring operative treatment, prevailed during Roman times and the long period in which there was little or no advance in surgical knowledge. During the Arabian ascendancy and through the time of Roger of Salerno, the establishment of the European Universities, and the Renaissance the same ideas prevailed in Italy, France and England. The methods of dressing and the types of local application were considered to be of great importance.

In the sixteenth, seventeenth and eighteenth centuries, important writings are associated with the names of Ambrose Paré, Pettit, Percival Pott, John Hunter and Larry Abernethy. Hunter's successor sounded a note of caution to the radical surgeon, and the nineteenth century was filled with divergent opinions. It is surprising that, before the days of antiseptic surgery there was not a greater weight of opinion on the non-operative side. Following the period of Lister there was more general agreement upon the desirability of elevating depressions, and, in a general way this tendency has continued to the present.

It is a common conception that depressed fractures of the skull are responsible for a degree of generalized brain compression which is dangerous. Even more often it is said that untreated depressions cause progressive brain damage, leading to pachymeningitis adhesions, areas of cerebral softening and brain cysts. It is asserted frequently that depressed fractures should be elevated to prevent the later occurrence of con-

vulsive states, mental derangement and psychoses. When such conditions are associated with the presence of a depressed fracture, surgeons are prone to attribute them to the depression and to advise that it be relieved surgically. It seems timely to consider the results of this policy for surgeons of experience have become aware that operations in such conditions do not yield brilliant results and usually are fruitless.

It may be said at the outset that the governing principles in the management of any depressed fracture should be first, to prevent infection, and second to minimize the amount of brain scar and the number of sequelae resulting from scar and adhesions.

The factors which come into play when a depressed fracture is produced must be distinguished clearly. Depressed fractures of the skull, without dural laceration, may be associated with varying degrees of brain injury. These will be considered in one group. Depressed fractures of the skull with penetration of the membranes inevitably lead to brain damage, also of varying degree. These will be discussed separately.

Let us first consider those depressions which have not penetrated the dura. It is customary to elevate such depressions when they are seen shortly after injury for patients with depressions of long standing also, this is the usual advice. If one has operated upon many persons with depressed fractures of long standing, and has opened the previously unpenetrated dura to inspect the condition of the underlying brain, he cannot fail to be impressed by the number of instances in which an apparently normal brain is uncovered, even though the depression has been present for years. Obviously this is not always true, and a yellow or degenerated cortex may be seen. The point of particular interest is that this is not invariable.

Questions immediately arise. Is a continued depression harmful? Does such a depression produce changes in the underlying brain by its mere presence, or is the brain change seen beneath certain of the depressed fractures caused by the

injury itself without reference to the continuance of the depression?

The desire to solve these two questions led us to undertake certain experimental work on animals some time ago. This work has been reported previously.¹ The experiments showed clearly that a depressed fracture, caused by striking a blow, produced both early and late pathological changes. Depressed fracture produced by pressure alone did not cause such changes. These depressions produced by the insertion of smooth foreign bodies into the skull caused no changes other than some condensation of the brain tissue beneath them nor was there any difference in the microscopic findings in the brains of animals sacrificed in 2 days after the depression had been introduced and those killed much later. If the foreign bodies were removed, later examination showed a rapid restoration of the contour of the brain and there was no evidence of a condensation of brain tissue at the location of the previous pit. Following the production of depressed areas by slow localized compression, neither pachymeningitis leptomenigitis, adhesions softening nor cysts were produced.

Our final conclusions were that, in cases of depressed non-penetrating fracture of the skull, the changes in the brain are caused by the force producing the injury rather than by the depression of the bone. Pathological changes in the brain appear to be more marked in the early and in the late stages than they do during the intermediate period, they are chiefly subcortical. Depressions of moderate size cause no pathological changes in the underlying meninges and brain.

If for the time being we consider only those depressed fractures in which there has been no dural injury, the question arises: Should such depressions be elevated? If this inquiry is examined in relation to the production of late changes in the brain, there seems to be very little reason for the operation. Likewise, there can be little sound basis for the argument that encroachment upon the intracranial chamber by reason of the depression, is sufficient to cause generalized signs of brain compression. If generalized brain compression is present, it results from other factors such as free hemorrhage. For the comparatively slight encroachment of a bone depression into the intracranial chamber, displacement of blood in the vessels and absorption of cerebrospinal fluid permit adequate compensation. Certainly there is no urgent reason for the elevation of a depres-

sion because of a conception that the depression itself is causing generalized intracranial pressure.

Another point may be raised. If a depression remains, may it be a source of mechanical irritation to the underlying brain by reason of the projection into the dura which it causes even though it does not produce degenerative changes in the brain? This is quite possible and we should hesitate to advise against the elevation of smooth depressions, even if we were sure that the dura had not been penetrated. However we feel safe in saying that in the presence of a depression without laceration of the dura, the immediate operations which are conducted so often, frequently with the patient in a precarious condition are not justified. In such instances one too often sees a patient brought into the hospital in a condition of shock, transferred from an ambulance to an examining table, changed again to a stretcher and transported to an X-ray laboratory where he is moved back and forth in the process of taking pictures then he is hurried to an operating room and an emergency operation is performed. Frequently little consideration is given to the advisability of using local anesthesia and the general condition of the patient is such that a hurriedly planned procedure is done. Less than the usual painstaking care is exercised, and less attention is given to details there is more hemorrhage at a time when the patient can ill afford to lose the blood than would have been the case with a more orderly preparation after the patient had recovered from shock.

The character of the treatment and the time it is instituted depend upon the condition of the patient and the presence or absence of an open wound. In a closed depressed, non-penetrating fracture, the time of operation is elective. Each case requires individual judgment. The only part of the treatment that is urgent is the prevention or control of infection. In some instances this involves relief of the depression in others it may await a later attack. When the depression is elevated, the bone should be replaced so that no permanent defect will remain.

Determination of dural penetration usually is made by roentgen examination, but this is not so urgent that it needs to be done during the period of shock. One point in X-ray examinations is overlooked so frequently as to merit comment. It is customary to make the diagnosis from films showing anteroposterior and lateral views of the skull. All the details of a depression and its depth can not be judged from these. Views should be requested which show the exact area of depression in true profile. To obtain these, the rays between

¹Naffziger, Howard C., and Gleason, Mark A. An experimental study of the effects of depressed fractures of the skull. *Surg., Gynec. & Obst.*, 1930, 10, 7-30.

the tube and the film should be exactly tangential to the area in question.

If we turn now to a consideration of the instances of depressed fracture with penetration of fragments through the dura and into the brain, a much more serious situation confronts us. A large proportion of these fractures are open, and the additional hazard of infection of the nervous system enters our calculation.

In the management of such injuries the presence or absence of an open wound and the length of time between the injury and the surgeon's repair bring in factors which can be judged wisely only by a competent surgeon at the time the patient is seen. Under ideal conditions, thorough surgical repair under local anesthesia with careful debridement of the scalp and other devitalized tissues, is desirable. In cases of open fracture such treatments cannot be deferred very long. In dealing with a closed fracture even if there is laceration and penetration of the dura by fragments, there is more latitude of action. Frequently when the general condition of the patient is poor postponement of such an operation for several hours or even for a day or two is a matter of good surgical judgment.

Wagstaff's follow-up of 280 patients with penetrating wounds of the dura showed that convulsive states followed in 28.7 per cent of them. In non-penetrating wounds, the incidence of fits was only 1.6 per cent.

In the light of our present knowledge of post traumatic convulsive states, our best opportunity of benefiting the patient lies in such careful repair that a minimal amount of scar tissue results.

In such surgical repair of penetrating injuries, a point that I wish to stress especially is the desirability of thorough removal of all devitalized brain tissue and of such additional tissue as has been contused sufficiently to indicate that its organization and repair will lead to a considerable cicatrix. After the removal of foreign bodies, the sucking out of devitalized brain and the tying of small cortical vessels in the region with resection of contused surfaces, will be repaid by lessening of the subsequent scar adhesions and contraction of the area, and consequent lessening of distortion

and deformity of the surrounding brain and ventricles which they cause.

Following the removal of loose penetrating fragments and of the devitalized area of brain, the importance of dural repair should be stressed. This is not always easy and extensive dural lacerations frequently demand that some new tissue be grafted in to fill the defect. Minor dural lacerations ordinarily can be closed with fine needles and silk. The larger lacerations may require the use of a bit of tissue from the temporal fascia or the pericranium to give a smooth covering. Failure to make such a complete dural closure may be justified at times, for instance when one is dealing with an open fracture, especially when the operation is performed some time after the injury, and there is evidence of infection. Such a set of circumstances is, however very unusual, and, in the earlier cases of both open and closed fractures, dural repair should be the rule. When such closure is not made complications are frequent. Occasionally protrusions of the brain through the opening will occur a considerable extrusion beneath the scalp may ensue, and ultimately there is likely to be a fungus, with the attendant difficulties of long-continued dressings and delayed healing, or death may occur as a result of the rupture of a ventricle, an abscess, or meningitis. Such protrusion of brain through a dural defect is, of course particularly likely to occur when there has been widespread brain contusion and resulting edema.

Skull defects may be avoided by replacement of the bone following the repair of the brain and dural injuries. Such replacement is desirable whenever possible.

CONCLUSION

There is experimental and clinical evidence to indicate that a depressed fracture of the skull is not so harmful as has been considered generally. The trauma producing the depression causes the damage to the brain. Our efforts must be directed toward lessening the risk of infection, toward diminishing scar tissue formation in the brain, and toward avoiding skull defects as far as it is possible to do so.

THE EXACT RÔLE OF PHYSICAL THERAPY IN THE TREATMENT OF FRACTURES¹

CLAY RAY MURRAY M.D., F.A.C.S. NEW YORK

Assistant Professor of Surgery College of Physicians and Surgeons, Columbia University; Associate Attending Surgeon Presbyterian Hospital in the City of New York

THERE is today in the minds of many the impression that the net result of the use of physical therapy in the treatment of fractures is to prolong the patient's convalescence. Whether or not this be universally true the fact is that it is true often enough to warrant serious consideration of the real value if any of physical therapy in this field and the proper rationale in its use if it is to be used.

In order to evaluate the exact rôle of physical therapy in the treatment of fractures it is essential that we first lay down the rationale which should govern all fracture treatment.

Our aim in fracture treatment is to restore a given individual to his normal habit of work or play as soon after his injury as possible and in as nearly normal an anatomical and physiological state as possible. Broadly this may be said to be our aim in the treatment of any human ill. But in the treatment of injury we face a problem with which we are not often forced to deal consciously in disease. That problem is the necessity of the patient's co-operation in the treatment if it is to be successful either in its final aims or in the time taken to accomplish them. In a case of pneumonia or of appendicitis the patient is a relatively passive agent and resumption of function in the affected organs depends largely upon automatic mechanisms independent of the patient's active efforts. In a fracture on the other hand though we may make the bone straight and hold it so until it has healed the only mechanism whereby the normal use and activity of the part may be rapidly regained whereby the strength and suppleness of the part may be restored is the active, voluntary use of the part by the patient. In any group of cases the question of whether or not we get rapid functional return in any given case depends all other factors being equal, almost entirely upon how early we get this active functional exercise on the part of the patient, and upon how generous he is with his efforts. To a larger extent than is commonly appreciated the functional end result is also dependent upon these same factors. It may be stated categorically that prolonged and slow functional recoveries are prone to be less complete than those that are relatively rapidly accomplished.

The ideal fracture treatment would be to wish the bone fragments into place, with the abolition of all pathology, and to hold them by force of will until the fracture was healed, while the patient went about his normal life without interruption. Translated into clinical terms this means reduction with as little attendant violence and damage as possible, early abolition of as much pathology as possible, as little interference on our part with function as possible during the bone healing process and as much functional activity as possible on the part of the patient. In any given case that method of treatment is best which can with safety most nearly fulfill these requirements.

It is obvious if we grant the validity of the preceding analysis that any given procedure can be of value only in so far as it aids in the accomplishment of one or more of these general aims of treatment. To assign to physical therapy any exact rôle in the treatment of fractures it is obviously necessary to be able to state what effects it can produce where those effects may be of value and how they may be best elicited; i.e. what methods of physical therapy are best employed.

First let us consider what effects physical therapy can be justly assumed to produce. I express a personal opinion, although I am certain that it is held by many others who have watched the development of the treatment of fractures when I say that much has been said and written of the mode of action of various physical therapeutic agents that is unfounded in fact and without other reason than unsupported theory or vivid imagination. I believe however, that we know that physical therapy can accomplish certain things, if properly and intelligently applied. It can relax muscle spasm; it can relax vascular spasm. I feel that our certain knowledge stops there. There are obvious secondary results of these two actions which we must logically recognize. Relief of pain and soreness, increased blood vascular and lymphatic circulatory efficiency, increased local metabolic activity are natural and undeniable consequences. I believe that these are the only effects which we are justified in depending upon in fracture treatment, with one excep-

tion which I shall mention later. How are these effects accomplished? There is again in so far as I can see no need to go far afield for abstruse explanations. There is no justification and indeed no need for talk about a little understood electrical force applied in the form of the static brush "pushing and forcing exudate out of the tissues", or of the part played by the electrical nature of diathermic heat in the production of its effects.

If one stops for a moment to consider the wonderful character of the human neuro-muscular and neuro-vascular reflex mechanisms, and of their activation by sensory impulses of a wide variety central as well as peripheral one can readily realize that the sensory effect of any given agent can well be responsible for resulting relaxation of both muscle and vascular spasm. And it is purely upon these two effects of physical therapy that we can depend for help in the treatment of fractures. The one exception to this statement lies in the use of muscle stimulation. There have been in use for many years various modifications of the electrical current for its effect in the production of muscle contractions. The earlier forms, in which both faradism and galvanism were used produced muscle spasm rather than a normal muscle contraction and constituted therefore a handicap rather than a benefit. There have been developed however through the use of rapidly interrupted galvanism associated with a surge variation apparatuses which can approximate the normal muscle wave of contraction and relaxation without spasm, although they can never equal the human mechanism in efficiency. One may consider this as a possible substitute imperfect to be sure for voluntary muscular activity by the patient in evaluating physical therapy in fracture treatment.

We may say that there are three elementary and basic forms of physical therapy available in fracture treatment—heat, massage, and muscle exercise. The first two are dependent for their effects on the relaxation of muscular and vascular spasm, and their action is wholly through the sensory arc of a reflex mechanism. It depends almost entirely on the pleasurable sensory effects produced. The third is of value largely for its pumping effect on the lymphatic and venous circulatory mechanism of the part as a whole, and in part for the artificial functional activity which results from its use. To these may be added the factor of moderate elevation as a circulatory aid. This elevation depends for its effect on gravity and it must not be of sufficient degree to interfere through this factor with the arterial inflow to the part. It should merely be sufficient to aid the lymphatic and venous drainage from the part.

The minute that one of these procedures causes pain or discomfort it ceases to be of value, and becomes a liability rather than an asset since it produces the very things we are trying to avoid—muscle spasm and vascular spasm. Heat is best applied therefore in an intensity low enough to produce merely the pleasurable effects of heat. Reddening of the skin is no criterion of the effect of heat. The patient's sensations are the only reliable criterion for intensity and length of treatment. Massage produces its effects through the pleasurable sensation it gives, and not through the force with which it is applied. Its results are due to relaxation of spasm and not to any mechanical milking or violent stimulation of the part. The gentler it is, the more regular it is the slower it is, the more uniform it is in force and direction the more pleasurable the feeling the more marked the relaxation of spasm. The stimulation of muscular contraction can be of no use if it is characterized by spasm. If it causes discomfort or actual pain or if it is carried on to the point of fatigue. Nor can it ever be of as much value as the patient's voluntary exercise of the same muscle.

There have been developed thousands of pieces of apparatus designed to cure the patient through the exercise of physical therapy. None of them is capable of doing more than evoking the mechanisms which I have cited. None of them is capable of accomplishing more in the way of relaxation of muscle and vascular spasm than is the use of heat and massage such as I have described, coupled with moderate elevation, competently and carefully carried out. Apparatus may spare the time and energy of the doctor may be made to replace lack of skill or practice on his part, may make it possible to take care of more people in a given time may exert some effect psychologically on the patient—good or bad—but it cannot accomplish anything which the doctor himself is incapable of accomplishing nor can it work through any other mechanism than that which I have described. A proper apparatus can offer a relatively inefficient substitute for the patient's voluntary muscular activity when it is either impossible or unsafe to secure voluntary active function. Any piece of apparatus, any so called modality is of value only in so far as it makes use of these principles. The whirlpool bath combines gentle massage and pleasurable heat. The static brush should provide the effects of pleasurable massage. Diathermy should provide the reflex effects of pleasurable heat. Intense diathermy producing all the heat the patient can stand, does harm. Intense heat of any other type does the

same thing. Vigorous massage is damaging if it gives the patient anything but pleasure. Muscle stimulation if carried to the point of spasm, discomfort, pain or fatigue is damaging. But so is voluntary exercise of the patient if carried beyond pain limits and up to fatigue. The physiological basis of the use of all of them is identical.

Here then lies one reason why the use of physical therapy frequently results in the prolongation of convalescence—in the lack of appreciation of the physiological principles back of its use and the failure to appreciate the simplicity of the mechanism involved. The fixed idea that the *physical therapist* must do something instead of the viewpoint that his real job is merely to make it possible for the patient to do it himself.

Let us now take the specific phases of fracture treatment and with this conception of physical therapy see if and where it may be of value.

1. The reduction. The use of light stroking massage of the type described by Lucas Championnière and Mennell or of any other agency which will produce the same results may be of definite value immediately following the injury and up to the time of reduction in helping to minimize the exudation into and infiltration of the tissues and in alleviating muscle spasm. It could well be combined with emergency traction to advantage in the period of inactivity between primary splinting and reduction if the facilities available make it possible.

2. The post reduction period. One of our objects in the treatment of a fracture is the early elimination of pathology before it can undergo organization into scar tissue. Immediately after a fracture there is hemorrhage and exudation and cellular infiltration in and about all the structures of the affected part. This pathology undergoes organization into tissue rapidly. Within 72 hours this organization is well started and by the end of 10 to 12 days it has progressed to considerable magnitude. In the first 5 to 10 days a large proportion of this exudation and infiltration can be removed from the part, before it can undergo organization, by any mechanism which will restore the normal circulatory efficiency of the part. It is here that physical therapy can be, I believe, of definite value in itself. If the method used in the treatment of the bone lesion allows of its use. Light massage of the character already indicated, heat of the type previously described or substitutes for them combined with moderate elevation can do much to aid in this early elimination of pathological processes. If it can be largely eliminated the amount of stiffness and soreness which will remain for later treatment and the amount of

late swelling on use and other circulatory handicaps due to scar tissue infiltration which will require attention will be greatly diminished and there will be less talk of the after treatment of fractures. To make it possible entails the use of methods of treatment for the bone lesion allowing of access to the part for physical therapy and the training of physical therapy technicians who know what we are trying to do and are capable in these early stages of giving the treatment with safety to the patient. I have met very few who are so trained. The maximum effect of such treatment is secured in the first few days. It loses its value progressively as the days pass by. Adequately and intelligently used I am convinced by practical experience that the convalescence time can be materially shortened. In addition I do not doubt but that the early restoration of adequate circulatory efficiency plays a large part in influencing the healing process in bone. Strangely enough it is in this phase of fracture treatment that physical therapy is rarely used and the development of its use by the physical therapists has been very much neglected. And yet it is only in this phase that it can play an essential part in treatment.

If the method of treatment or the nature of the injury allows of full function during this stage there is no use or need for muscle stimulation unless it be used as a substitute for active muscle exercise in a patient who will not give his voluntary help. If the method of treatment used is such that active motion cannot be used or is definitely limited muscle stimulation of the proper type can help greatly as a partial substitute. I should like to stress the point that the muscle activity desired in this instance is not the subminimal invisible contraction desired in the treatment of paralytic muscle, but is the maximal contraction obtainable without spasm or discomfort, and stopped short of fatigue. It is a substitute for the patient's active use of the part. Even in the presence of circular plaster or splints its use can be managed through the windows or apertures in the apparatus.

3. After treatment. After the bone has healed and the patient is in position to regain progressively the full use of the part is the stage in which physical therapy is almost universally used—and abused. There are certain definite facts which must be stressed before discussing the use of physical therapy at this time. No physical therapy that I am familiar with can restore strength and suppleness to a limb, regardless of who gives it, or what complicated and impressive machinery is used to carry it out. The only factor

essential in the regaining of functional activity by a patient is the voluntary active use of the part progressively by the patient. These facts are incontrovertible. The doctor who sees the case, the technician who administers treatment, and the patient who receives it must all know this fact.

Physical therapy may be used to make it easier for the patient to do his part by temporarily ridding the part of soreness and stiffness through the mechanism already described so that it is easier for him to use the part. It may be used to get rid of the unpleasant effects of overexercise—pain, soreness, stiffness, and swelling. But it cannot successfully be used to restore *per se* strength and suppleness to a part. The only way to strengthen wasted muscles permanently or to limber up stiff joints permanently is for the patient actively to exercise them. Physical therapy can do no more than make the voluntary function easier and less distressing. Here lies the second reason why physical therapy so often hinders the convalescence of the patient. He does not know that the heating, the rubbing, the various complicated appliances used cannot possibly make him well and for week after week and month after month he sits patiently waiting for this easy and effortless recovery to take place. I know that many of the physical therapists who treat this

hopeful but deluded patient are firmly convinced that they can get him well. And I have reason to believe that many of the doctors of these patients have never given a thought to what either the patient or the physical therapist know or believe. And physical therapy under such auspices becomes an idle and futile gesture, but unfortunately one in which the patient is taught to have infinite confidence.

There are here presented the grounds which exist for the belief that physical therapy can be of value in fracture treatment. The attempt has been made to show the basically simple *modus operandi* upon which all physical therapy is dependent for its effects, regardless of the complicated trappings in which it may be dressed. The attempt has been made to indicate when and how these effects may be of value. Attention has been called to defects in the present application of physical therapy to treatment of fractures which are widespread and which serve in many instances to delay convalescence rather than to hasten it. The solution lies in education—first of ourselves, next of our technical assistants, and lastly of our patients—to the realization that in treatment of fractures the thing that counts, apart from the actual reduction, is not what we can do for the patient, but what we can help the patient to do for himself.

THE SIMPLIFICATION OF THE TREATMENT OF FRACTURES

PAUL B. MAGNUSON, M.D., F.A.C.S., Chicago

THE simple methods which are applicable to the reduction and fixation of most fractures seem to have been pushed into the background during the last few years by the vast amount of literature advancing pet methods in operative treatment. It is true that a certain number of fractures should be recognized immediately as operative cases, but the decision as to whether or not a given fracture is operative should be made at once, and not delayed until a bad result has occurred. There are certain fundamental principles which should be kept in mind. Immediately a fracture comes to hand the structures of the anatomy involved should be visualized. Before the fracture is thought of as a pathological entity, the first step should be the mental picture of the attachments of muscles and the estimation of their strength, the angle at which they pull, and the amount of displacing effect they have on the fracture as it exists. The second step should be a thorough consideration of the equipment necessary for reduction of the fracture and the equipment necessary to hold it in reduction. This is fully as essential as having all operative equipment at hand and ready for immediate use before attempting any open operation.

The theory of reduction and proper retention of fractures is based on one principle—traction balanced by countertraction. The fragments must be held in alignment by counterbalancing the displacing effect of the muscles attached to them. In most cases this is simple. Open operation is unnecessary in the vast majority of fractures in my opinion. If the anatomy is understood, the physiology of the structures is taken into consideration and the details of the mechanics of reduction and retention are carefully thought out.

Many times traction for maintaining reduction is carelessly applied. Usually the best method of maintaining traction is by the application of adhesive plaster to the skin. It should not be applied as longitudinal bands but as three-tailed strips (Fig. 1) the wide center bands run directly up each side of the limb and the narrow side strips are wound corkscrew fashion around the limb (the anterior strips being crossed and wrapped around from front to back and the posterior strips from back to front). This eliminates straight downward pull on the skin, grips the limb circu-

larly, does away with much skin irritation and allows greater weight to be applied with less discomfort. Almost any fracture can be pulled into line if skin traction is applied in this way with due consideration for the parts involved.

The manual reduction of fractures is ill advised as a general rule, because the strength of the muscles attached around the fracture is greater than the force which the operator can apply by manual manipulation. The operator's muscles tire and pass from tonic contraction into clonic contraction. Jerky motion will irritate the tissues about the fracture and cause reflex spasm in the muscles which further interferes with proper reduction. Any effort at reduction should be steady, strong and prolonged to the point where the patient's muscles are tired out and relaxed sufficiently to permit the fragments to be brought into alignment and this can be accomplished only by mechanical means which relieves the surgeon of strain and frees his hands to manipulate the fragments until the ends can be approximated and forced into contact. Therefore in every fracture provision should be made for applying slow, steady and prolonged traction.

In fracture of the arm when the line of fracture is transverse or nearly so, immediate reduction may be made by means of a heavy muslin bandage looped around the patient's wrist or elbow and passed over the surgeon's shoulder (Fig. 2). The patient is secured to the table by a bandage placed around the chest under the axilla, thus fixing him firmly on the table and permitting the kind of traction necessary. Traction always calls for countertraction and this countertraction should be arranged for before traction is started. With the bandage loop around his shoulder the surgeon may press his foot against the cross bar between the legs of the table and use his weight against the bandage to apply traction. He is under no strain, both hands are free, there is no interference with his sense of touch, and the pull can be continued until the patient's muscles are thoroughly relaxed when the reduction can be accomplished with ease.

Strong traction may be applied in fracture of the leg by a Collins hitch (Fig. 3) placed around the ankle and a double pulley fastened under the sole of the foot by tying the ends of the hitch through the eye of the pulley. Another double pulley is attached to the foot of the table, and the

Fig. 1

two are joined by a piece of clothesline. Here too countertraction must be provided, the simplest method being to pass a sheet between the patient's thighs and tie it to the head of the table. Tremendous traction may thus be applied without any marked exertion on the part of the surgeon, who is free to manipulate the fragments while an assistant increases the traction as directed.

All is not finished however when the fracture is reduced. The application of a cast or splint while maintaining the fracture in position is no mean feat and must be carefully planned before reduction is started. Many fractures have been displaced after proper reduction because of improper handling by an assistant while the surgeon was engaged in applying the apparatus. No man can hold a weight in his hands for 15 minutes, or 10 minutes or even 5 minutes in exactly the same position, and the danger of inadvertent movement is increased by the number of hands supporting the injured member. Fractures must be reduced mechanically and must be maintained mechani-

Fig. 2

cally and the mechanics of applying the retention apparatus must be arranged beforehand, or the case may come to grief. It is a difficult matter to apply a cast or splint without an assistant, and in many cases the assistant at hand is not skilful, is frequently nervous, and cannot be depended upon to do exactly the right thing at the right time.

In a fracture of either the leg or arm it is sometimes necessary to maintain traction while the

Fig. 3

Fig. 4

Buttock over edge of table

Fig 5

Fig 6

cast is being applied. If the limb is in a horizontal position, steady support should be given above and below the fracture as well as at the point of fracture in order to prevent angulation. For the leg a wide muslin sling supported from a horizontal bar above can be applied in such manner as to eliminate the possibility of angulation after the fracture is reduced, and permit maintenance of traction in any given line and in any given amount. This sling is made with a piece of muslin equal in width to the length of the member to be supported. It is torn in 4 inch strips from each end to within 4 to 6 inches of the middle, leaving the center section intact, thus forming a sling. The narrow strips of which tied to a horizontal bar above the limb can be adjusted at any desired point to form a smooth and firm support over the entire length. Traction can be continued by a Collins hitch below and above by the use of either pulleys or weights. The cast is applied over this muslin support the bandage being passed between the strips and made continuous over the entire posterior surface of the leg. When the plaster is firm enough to preclude the possibility of bending, each alternate strip may be cut loose from its overhead support and the application of plaster continued. When the cast is completely hardened the remaining strips may be cut from the overhead support and the windows in the cast

which remain as a result of surrounding the strips with plaster can be covered.

In the application of plaster where the limb can be fixed perpendicularly as in the forearm traction can be made by passing loops around the fingers and attaching these loops to an overhead support. If the weight of the arm does not afford sufficient countertraction a sandbag thrown over the lower end of the humerus just above the elbow will give all the countertraction necessary to maintain the fragments in position.

In maintaining inversion in fractures above the ankle, particularly in Pott's fracture and fracture of the os calcis, it is frequently difficult to rotate the foot inward and maintain this inversion without denting the cast at some point as inversion must be maintained by pressure of the assistant's or the operator's hands. Here it is advantageous to protect the foot with a heavy felt pad with a few turns of plaster bandage around the ankle bringing the plaster down from the ankle over the outside of the foot, under the sole and up toward the knee on the inner side. An assistant grips the bandage roll in one hand, and while supporting the leg with the other hand maintains the knee in right angle flexion supported against his chest (Fig 4). If the bandage is passed around the foot immediately under the astragalus the foot will be inverted at the subastragaloid joint, the location

Fig. 7

where inversion should take place. Inversion is easily maintained and the operator's hands are free to apply the cast. Grasping the ball of the foot to turn the toes in merely inverts the anterior part of the foot, but does not invert the subastragular bones.

Casts applied for fractures or injuries in or near the knee joint frequently do not accomplish their purpose—namely immobilization—because the cast is not applied so that it will give equal leverage on both sides of the fracture. The extension of the cast down onto the leg toward the foot can be carried out simply and easily but the application of a long cast to the thigh is not so simple. The muscles around the thigh are heavy and immobilization is impossible unless the cast is made very snug, and if the cast does not extend as far above the fracture as below the immobilizing effect is not good. Therefore where it is desired to immobilize the knee or to support the femur after a fracture of this bone has healed, the patient should be drawn well over to the side of the table and the leg should be brought into full abduction (Fig. 5). The top of the cast may then be brought up into the gluteal fold and up against the ischium thus giving as long a lever above the knee as below. If the upper and lower ends of the cast are well padded with sheet wadding and the stockinet is rolled back over the sheet wadding after the cast is applied, there is ample protection of the soft parts from pressure (Fig. 6). A walking caliper can be made by placing a U shaped piece of iron under the foot, the uprights of the iron being included in the lower end of the

Fig. 8.

cast on each side of the leg. The ischium will rest on the pad at the upper end of the cast and the weight will be transmitted to the iron.

In fracture of the surgical neck of the humerus when it is necessary to maintain traction to reduce the fracture, the apparatus used should center in its motion exactly under the glenoid fossa. Traction should be started with the arm in about 30 to 35 degrees of abduction and the elbow gradually be brought forward as the arm is abducted. If the arm is immediately abducted and put in traction, the upper end of the lower fragment is thrown downward and forward as the elbow is brought outward, because here the attachment of the pectoralis major acts as a fulcrum, and until this muscle is either relaxed or stretched the lower fragment cannot be brought down into position (Fig. 7).

Fractures of the lower end of the humerus into the elbow joint probably give as unsatisfactory results as any class of fractures. This is due to several factors. In the first place, the bones of the forearm articulate with two almost completely separate joints on the end of the humerus, and when fracture into the elbow joint occurs these joints are separated. The muscles attached to the lower end of the humerus have a tendency to displace the fragments in different directions. The centers of the two condyles around which the radius and ulna rotate on the lower end of the humerus normally are exactly in the same axis, but when the condyles are fractured the alignment

Fig 9. (See Fig 10)

of this axis is disarranged and is very difficult to re-establish because the humerus just above the condyles is extremely thin in its anteroposterior diameter while its lateral diameter is widened (Fig 8). Open reduction of such fractures is not satisfactory as a rule because it entails considerable damage to the ligamentous attachments around the elbow. Furthermore, it is very difficult to fix the two condyles to the lower end of the humerus on exactly the same pivot, because the lower end of the upper fragment, which articulates with these two condyles is so thin from front to back that it is next to impossible to drive a peg or nail from below upward and have any stability between the fragments. If they are wired the wire does not hold them in firm enough position to maintain the true axis, and as they heal there is apparently a great tendency for excess callus to form which further contributes to blocking of the joint. These fractures can be reduced and maintained in reduction much more satisfactorily by traction applied in a very simple way.

The treatment is based on the fact that the ligaments attached to the condyles of the humerus and the radius and ulna will pull the fragments back into their normal centers and alignment, if the muscles attached to the condyles are balanced and relaxed. Therefore the forearm is suspended at right angles to the humerus with just enough traction applied to hold the elbow clear of the bed, thereby permitting the pronators and supinators of the forearm to find the position in

Fig 10

rotation in which they balance each other. Beneath the muscle attachments are the ligaments and the capsule attached to the fragments. If traction is applied to the forearm with the elbow flexed the lateral ligaments and the posterior ligaments are pulled tight. If continuous traction is made over the upper end of the forearm near the elbow with the elbow flexed the anterior capsule is stretched tight as well as the lateral and posterior ligaments and thus pulls all the fragments of the lower end of the humerus into fairly normal relation with the radius and ulna, and re-establishes the relation of the axis of both condyles.

The procedure is simple and is easily carried out by cutting felt in a pattern which will fit closely around the elbow on its flexor surface. With traction applied to the felt close to the elbow joint, immediate traction can be transmitted to the fragments through the ligaments and muscles of the forearm at the elbow (Figs. 9 and 10).

Fractures of the olecranon always require open operation if the fragments are separated and the ligaments torn which is usually the case. These fractures can be fixed in such a way that immobilization is unnecessary. The usual custom is to drill through the upper end of the lower fragment and through the middle of the upper fragment passing kangaroo tendon, silk or wire through the two holes to fasten the fragments together. Can cancellous bone does not stand as much pull without atrophy as do the heavy attachments of the muscles. The triceps tendon is attached to the olecranon, and if malleable iron wire is used (which is the strongest form of wire with which we are familiar), the wire can be passed through the triceps tendon posterior to the long axis of the olecranon and ulna, and fastened to the lower fragment which is composed of hard cortical bone (Fig 10). If the fragments are held together in

Fig. 11

this way the pull of the triceps muscle is transmitted through the wire directly to the lower fragment, and any angulation at the posterior end of the fracture line is prevented. If the wire is put in line with the axis or anterior to the line of the axis, the triceps tendon has a tendency to separate the fragments at their posterior junction, and if they heal in this position extension is limited because the olecranon is pulled upward and into the olecranon fossa.

Motion can be started within 24 hours after

operation in these cases, and union should be complete in from 4 to 6 weeks without disability in the elbow.

Fractures of the forearm, which are probably more difficult to reduce than any other fractures in the body in many instances should not be treated as ambulatory cases. When there is serious displacement, reduction by manual manipulation is usually impossible. The fascia surrounding the muscles of the forearm is strong; the muscles are extremely active and tend to con-

Fig. 12.

tract and maintain the fragments in malposition. There are no fractures which need steady continuous tiring traction more than do fractures of the forearm. Serious disability results if union is permitted with angulation or abnormal rotation between the radius and ulna. Disability of the forearm means disability of the hand, because the dexterity of the hand is dependent to a great extent upon the integrity of the bones of the forearm.

In order to maintain traction on the forearm it is necessary to apply some form of countertraction inasmuch as the weight of the upper arm is not sufficient to overcome the pull of the muscles. Therefore the forearm should be placed in suspension. An adhesive plaster cuff is placed around the wrist, attached to horizontal strips of wood at the level of the metacarpophalangeal junction. Countertraction may be applied by placing a sandbag of the requisite weight across the lower end of the humerus just above the elbow. Rotation of the radius may be controlled by attaching to the horizontal crossbars a rope which controls this motion. When sufficient traction has been attained to bring the fragments into alignment they may be supported by double board splints on the flexor and extensor surfaces (Fig. 11).

In fracture of the radius without fracture of the ulna, there is in addition to the deformity a disarrangement of the radio-ulnar joint at the wrist. As the radius shortens, the relation of the radius and ulna at the wrist joint is changed, the hand is pulled into radial flexion, and the ligaments which support the radio-ulnar joint are either torn or stretched. In every fracture of the radius without fracture of the ulna normal length of the radius with normal relation of the fragments so far as rotation is concerned must be re-established in order to re-establish complete function in the hand and wrist. Even with restoration of normal length in the radius, there is

Fig. 13

sometimes severe injury to the ligaments holding the two bones together which will result in serious disability if not given special support. Relaxation of this joint may occur which will leave a serious disability so far as the strength and the dexterity of the hand are concerned. After such injury, therefore, whether it be fracture in the shaft of the radius or Colles fracture this joint must be supported and this can best be done by placing a thick felt pad laterally over the radius and over the ulna allowing each of them to fold around the flexor and extensor surfaces. The two pads are then forced toward each other by including them in a tightly strapped circular band of adhesive plaster. It is impossible to put a circular band snugly around the wrist unless the flexor and extensor surfaces are protected from pressure because it would interfere with circulation and cause swelling and congestion in the hand but with thick pads applied laterally this is prevented, as the adhesive plaster does not touch the flexor and extensor surfaces (Fig. 12).

Probably the most common fracture with which we have to deal is Colles. In this fracture there is a backward and upward displacement of the lower fragment, and the fragments are usually rather firmly impacted. When the lower fragment moves backward and upward it carries backward with it the annular ligament. The lower articular surface of the radius is carried backward and upward, and, in a typical deformity, instead of the lower end of the radius facing toward the flexor surface, it faces toward the extensor surface. This deformity also produces a double bend in the flexor tendons, forcing them under the lower end of the upper fragment where they are kinked rather sharply backward to pass toward the fingers under the annular ligament, which has been carried backward. This double bend, in tendons which should run straight from the muscles from which they originate to the bones to which they

Fig. 14

are attached diminishes the strength of the pull of the muscles (Fig. 13). In addition the hand is carried into radial flexion by the shortening of the radius, and the radio-ulnar joint is disarranged. Unless this deformity is corrected unless the lower fragment is brought into correct apposition with the upper fragment, the double bend in the tendons removed and the lower articular surface of the radius brought into proper angle with the long axis of the radius (namely facing slightly toward the flexor surface) three serious disabilities occur. First limitation of supination because of the disarrangement of the radio-ulnar joint; second limitation of flexion of the wrist, because of the change in the angle at which the lower fragment articulates with the upper; and third, diminution in the strength of the hand because of the displacement of the lower fragment plus the double bend in the flexor tendons at the wrist and possible adhesions.

Reduction is easily carried out, and the earlier the better. Traction should be applied over the base of the hand by a bandage loop extending from the hand over the operator's shoulder. First the impaction should be broken up. With the thumbs over the ends of the fragments on the extensor surface of the lower end of the radius, the deformity should be increased until the fracture is perfectly loose and the fragments move freely on each other (Fig. 14). Until complete breaking up of the impaction is brought about traction is useless, but when it is accomplished longitudinal

Fig. 15.

traction on the arm will bring the lower fragment down to a point where its fractured surface is at a level with the fractured surface of the upper fragment. Pressure forward with the thumbs on the lower fragment, and backward with the fingers on the lower end of the upper fragment, will then force the fragments into alignment and bring the articular surface into its normal position (Fig. 15).

In elderly patients it is sometimes impossible to re-establish the normal length of the radius, because in the impaction there has been an actual disintegration of cancellous bone cells, resulting in a loss of bone substance which permanently shortens the radius. In these cases some deformity will remain.

No one method can be made to apply to all cases, even those of the same type. Variations must be made according to the needs of the case. When dealing with fractures one is dealing with a problem in mechanics. A fundamental knowledge of the anatomy and physiology is as important in dealing with the stress and strain on the fractured fragments as is the knowledge of physics to an engineer in undertaking a problem of purely mechanical construction. The main difference is that the surgeon must take into consideration the fact that power and breaking force are applied to a fracture during 24 hours of the day, because the muscles continue to contract until they encounter resistance which will counterbalance the strength of their pull. The surgeon also has the additional problem of not being able to exert enough mechanical force directly on the part to be treated to bring it into alignment and maintain it in alignment without the hazard of injuring living tissue.

Fig. 16 Anterior and lateral views of comminuted fracture of lower end of the humerus into the elbow joint. The same 24 hours later after the application of extension.

Therefore ingenuity and ability to meet individual requirements are much more important in dealing with a fracture than in the average engineering problem.

In the methods given herewith only such mechanical apparatus has been described as can be improvised from materials to be found around almost any farmhouse. These methods are not advocated as the only means of handling such problems but are advanced to point out the fun-

damental principles of treatment of certain fractures and they can be varied by the ingenuity of the surgeon to meet the requirements of any given case. As stated in the beginning of this article there are certain fractures which cannot be reduced and maintained in reduction satisfactorily without open operation but the differentiation should be made early in the case and not be postponed until faulty union or nonunion has resulted.

THE RUSSELL EXTENSION METHOD IN THE TREATMENT OF FRACTURES OF THE FEMUR

A REVIEW OF THE ANATOMICAL RESULTS OBTAINED IN A GROUP OF FIFTY-ONE CASES

WALTER ESTELL LEE, M.D. PHILADELPHIA J ROSS VEAL, M.D. NEW ORLEANS, LOUISIANA

In 1923 R. Hamilton Russell of Melbourne Australia, first published his report of a method to obtain reduction of the fragments in fractures of the femur. "This employs a natural and comfortable position of the extremity in which but a relatively small amount of traction is required to restore the balance or equilibrium of the muscles of the thigh when it is applied distally to the knee joint."

In 1927 Ryan of Philadelphia called attention to this method, reporting 8 cases. In 1930, Ridgely and Bongardt 15 cases. In 1930, Jopson and Brown 42 cases and in 1931 Lund published his end-results in 27 cases.

At the Philadelphia meeting of the Clinical Congress of the American College of Surgeons in 1931 Summey demonstrated the end-results of a group of 58 cases of fractures of the femur treated by Russell's extension in which there was but one case of non union caused by the interposition of muscle and requiring open reduction. This work has never been published.

Following this report of Summey we decided to use this method in the surgical services of the Graduate Hospital of the University of Pennsylvania, the Pennsylvania, Bryn Mawr German town and Burlington County Hospitals.

The impression made on Scudder by our first report, together with his knowledge that we were using this type of extension almost routinely in our five hospitals, may be responsible for his invitation again to review our results.

The fact that 10 years after the publication of Russell's article we have been able to find in the literature records of but 87 cases treated by this method containing the data required for a critical analysis has been a surprise.

These reports are uniformly favorable and Lund expresses the opinion of the others in saying "I have been impressed with the ease of application of this method and by the comfort it affords the patient. It facilitates the dressing of compound wounds and makes easy daily inspection and measurement. Early massage and other physical therapeutic measures may be given together with excellent care of the soft structures and adjacent joints. The end results have been excellent, and a minimum of residual disabilities of the joints have occurred compared to those following other methods." In but one of these reports is there any warning of its limitations and this is found in the original article of Russell. The apparatus is far from fool-proof and cannot and will not look after itself.

Two definite impressions developed very early in this study and became more fixed as the work progressed. (1) That the results obtained in these five hospitals were far from uniform. In fact, they varied so much that it was a matter of general comment. (2) That the average of the anatomical results was not as satisfactory as we had believed it to be.

We have been forced, therefore, to admit that the impression one receives from the literature that it is so simple of application and so easy to

maintain that it is almost fool proof has not been borne out by our experience. That it is possible to obtain the excellent results exhibited by

other surgeons has been demonstrated by us in this group of cases, but our results have not been uniform and if this report is to have any value it will consist not only in the exhibition of our failures, but also in the presentation of explanations of these failures. That we have been able to obtain the results reported by others as shown by the fact that 16 of these 51 cases have received a rating of from 90 to 100 per cent of anatomical restoration. Of these cases 7 were from Hospital A in which we consistently found the best results, but there were also 3 cases from Hospital B, 4 from Hospital C and 2 from Hospital D but none from Hospital E.

In the limited time allowed for the making of this survey it has been impossible to study all of the factors contributing to our final results, and we confined our efforts to an estimation of the anatomical restoration at the time of the patient's discharge from the hospital, feeling that this offers the best index of the efficiency of any method of extension or traction.

In estimating the anatomical restoration of these fractures of the long bones we have arbitrarily given 50 per cent for alignment, 25 per cent for end-to-end apposition, and deducted 25 per cent for overlapping.

Using this rating we found that the average anatomical restoration in the five hospitals was 70.5 per cent. The variations in the results in

the five hospitals is shown by the following tables (Fig. 2)

		Cases	Per cent
Hospital A	90-100 per cent	7	26.9
	80-90 per cent	5	26.9
	70-80 per cent	0	0
	60-70 per cent	0	0
	50-60 per cent	5	20.8
	Under 50 per cent	1	4.3
Hospital B	90-100 per cent	3	60
	80-90 per cent	0	0
	70-80 per cent	2	40
	60-70 per cent	0	0
	50-60 per cent	0	0
	Under 50 per cent	0	0
Hospital C	90-100 per cent	4	90
	80-90 per cent	1	11.5
	70-80 per cent	0	0
	60-70 per cent	0	0
	50-60 per cent	0	0
	Under 50 per cent	3	37.5
Hospital D	90-100 per cent	2	18.1
	80-90 per cent	1	9.9
	70-80 per cent	2	18.1
	60-70 per cent	0	0
	50-60 per cent	4	36.4
	Under 50 per cent	2	18.5
Hospital E	90-100 per cent	0	0
	80-90 per cent	0	0
	70-80 per cent	0	0
	60-70 per cent	2	66.4
	50-60 per cent	0	0
	Under 50 per cent	1	33.6

In an attempt to find more or less constant factors which would be operative in the five institutions and which would account for these variable results, we have analyzed (1) the age of

Fig. 2. Comparison of the anatomical reduction obtained by Russell's extension in five hospitals.

Fig. 3. Comparison of the results in growing and adult bones.

the patients dividing them into two groups, under 18 and over 18, with the classification of adult and growing bones (2) the character of fracture spiral oblique transverse or comminuted (3) the location of fracture intertrochanteric and subtrochanteric, upper third of the femur middle third of the femur lower third of the femur and supracondylar (4) the interval of time between the receipt of the injury and the application of the extension, using 12 hours as the minimum, (5) an estimation of the efficiency of application of the extension according to the principles outlined by Russell, or of failure to maintain these principles subsequent to its application and (6) the premature removal of the apparatus.

It seemed reasonable to divide these factors into two groups first, those over which the surgeon had no control and second those over which he should have had complete control.

The factors over which the surgeon had no control and which in our statistics appear to have

definitely influenced the results are (1) the age of the patient (2) the type of the fracture and (3) the location of the fracture.

The factors over which the surgeon should have had complete control were (1) the time elapsing between the receipt of the injury and the application of extension (2) the efficiency of the application of the apparatus and the success or failure to maintain the principles of Russell subsequent to its application and (3) the premature removal of the apparatus before solidification of the callus.

UNCONTROLLABLE FACTORS

Age Contrary to our expectations there was practically no difference in the anatomical reduction obtained in the growing (69.5 per cent) and in the adult (70.2 per cent) bones. We wish to make clear that this does not refer to the end-results or the functional results but to the anatomical restoration that existed at the time of the

Fig. 4. Effect of location of fracture on anatomical reduction by Russell's extension.

discharge from the hospital. The repeated statements of Ashhurst, Speed, and others, that shortening as a rule may be disregarded in early childhood and of Pfiester that he never saw a fracture in the shaft of the femur of a child that did not give a good result, applies to the final results in all of these fractures in growing bones (Fig. 3).

There is a wide range in the ages of the patients included in this study. The youngest was 4 years of age. His fracture was of the transverse type and was located in the middle third. There was an overlapping of 2 centimeters. Excellent reduction was obtained. The oldest patient was 79 years of age. Her fracture was also transverse in the middle third and had 4 centimeters overlapping. Excellent reduction was obtained.

In the growing bone group, i.e., patients below the age of 18 years there were 30 fractures. Six

of these were under 10 years of age. There were 12 between the ages of 10 and 15 years. Two cases were 16 years of age. Five of the fractures were in the upper third, and 15 in the middle third. Eleven were transverse, 4 were comminuted, 3 were oblique, and 2 were spiral.

The average time of Russell extension in this growing group was 35.4 days. The average stay in the hospital was 49 days. The final average percentage of anatomical reduction was 69.5.

In the adult group there were 31 fractures. Three were intertrochanteric, 4 in the upper third, 16 in the middle, 4 in the lower third and 4 were supracondylar. According to the type of fracture, we find 16 were comminuted, 9 were transverse and 6 were oblique. The average time in Russell extension for this group was 37.2 days, the average stay in the hospital, 66.1 days, the final average percentage of anatomical reduction 70.2.

Fig. 9. The R. Hamilton Russell method of extension. (From Brit. J. Surg. 1924-25)

Type of Fracture The best rating obtained was in the spiral fractures, next the comminuted, then the oblique, and the lowest rating was in the transverse fracture (Fig. 1)

Spiral fracture, average rating 95 per cent of anatomical reduction.

Comminuted fracture, average rating 79.5 per cent of anatomical reduction.

Oblique fracture, average rating 69.1 per cent of anatomical reduction.

Transverse fracture, average rating 63.4 per cent of anatomical reduction.

In analyzing the types of fractures in this series we find 5 were spiral 20 were comminuted 9 were oblique and 20 transverse. The two spiral fractures (Fig. 1A and B) were in growing bones and excellent reduction was obtained 95 per cent. The average percentage of reduction for the comminuted group (Fig. 1D and 3U) was 79 per cent, for the oblique (Fig. 1E) 69.19 per cent, and for the transverse 63.48 per cent (Fig. 1I).

Location of the Fracture. In this group of 51 fractures (Fig. 4) 3 were intertrochanteric, 9 were in the upper third 3 in the middle third, and 4 were supracondylar. The best results were obtained in fractures of the lower third of the femur 96 per cent in the intertrochanteric fractures, 80.3 per cent (Fig. 1C and D) the middle third of the femur 70.97 per cent (Fig. 1Q and R) and in the supracondylar fractures, 63.41 per cent (Fig. 1W X Y Z). The lowest rating was obtained in fractures of the upper third of the bone. Note the wide difference in results obtained in fractures of the upper and lower thirds. The short upper fragment in fractures of the upper third often caused anterior angulation. Excellent results were obtained in the intertrochanteric and lower third types. In one of the supracondylar fractures the distal

Fig. 10. Details of pulley arrangement at foot of bed. (From Brit. J. Surg. 1924-25)

fragment was anterior and perfect reduction resulted. In the others, however the distal fragments were posterior and unsatisfactory results were obtained.

CONTROLLABLE FACTORS

In analyzing the controllable causes of failure to obtain and maintain reduction we find three main factors were operative. The first of these was delayed application of the apparatus. By this we mean that extension was applied later than 12 hours after the fracture occurred. The second factor was improper application of the principles of Russell's extension. Here the apparatus was not applied properly or it was not maintained properly throughout the healing stage. The third factor was premature removal of the extension. By this we mean that the extension was removed before adequate callus had formed to maintain reduction. Premature removal often resulted in overlapping or angulation.

DEFORMITIES

As noted above we have allotted 50 per cent to proper alignment of the fragments, 25 per cent to full end-to-end apposition, and have deducted 25 per cent for overlapping.

In 19 fractures healing took place with some overlapping of the fragments (Fig. 6). The greatest amount of overlapping was 4 centimeters, the average being 2 centimeters. Seven, or 35 per cent, of these cases were in growing bones and 12 or 36 per cent, in adult bones.

In studying the causes of failure to overcome overlapping we find that in 52.63 per cent of the fractures it was due to delayed application of the apparatus. Improper application and maintenance

Fig. 11 The direction of forces. (From Brit. J Surg. 1924-11)

of the principles of Russell was responsible in 26.3 per cent, and premature removal of the apparatus in 21.05 per cent. The average days in Russell's extension was 26.7. The results noted above show clearly the importance of early extension.

In 16 of the total of 51 fractures there was either failure to obtain end-to-end apposition (Fig. 7) or to maintain it after the fracture was reduced. Seven, or 35 per cent, were in growing bones and 9 or 27 per cent, in adult bones.

In analyzing the causes of failure to obtain end-to-end apposition we find again that delayed application of extension was the most important single factor accounting for 43.75 per cent of the cases; improper application of the principle was second with a percentage of 33.35 per cent, and premature removal accounted for the remainder or 18.75 per cent. Average time in Russell's extension was 24 days.

Eighteen, or 39.2 per cent, of the cases of this series presented from 5 to 25 degrees of improper alignment. Six, or 30 per cent, were in growing bones and 12 or 36 per cent in adults. We have calculated the amount of improper alignment in degrees of angulation or deviation of the fragments from the normal weight bearing line. The average angulation was 14 degrees; the deviation 10 degrees. In 15 there was some angulation: 11 posterior and 4 anterior. Ten cases showed some deviation, 6 being external and 4 internal.

In analyzing the causes of the failure to obtain and maintain proper alignment (Fig. 8) we find that delayed application accounted for only 27.77 per cent. Improper application of the principle was the main factor here and accounted for 61.11

Fig. 12 The spreader used in Russell's apparatus (From Brit. J Surg., 1924-11)

per cent of the cases. Premature removal of the apparatus came last with a percentage of only 11.11 per cent of the cases. The average number of days in Russell's extension was 22.

In summarizing we find that delayed application was the most important factor in our failures to overcome overlapping and obtain end-to-end apposition of the fragments. Improper application of the apparatus was by far the most common cause of failure to obtain and maintain proper alignment.

It is interesting to note that all of the factors mentioned are easily overcome by adhering strictly to the principles laid down by Russell in his original paper. The Russell method of extension in fractures of the femur is described by him as follows:

The apparatus shown in Figure 9 consists in a sling beneath the knee and horizontal traction on the leg. The arrangement provides that the pull on the leg shall be nominally modified by the friction between the pulleys and cords. The special apparatus required is as follows:

1. An ordinary head-to-foot bar that can be shifted laterally as required. This can be fitted to the ordinary four poster bed, but a more convenient way is to use two uprights, one at the head and one at the foot, securely lashed to the bedstead. The foot of the bed should be elevated to insure counter-extension by the weight of the torso.

2. An arrangement to which may be attached a couple of pulleys beyond the foot of the bed. These pulleys (Fig. 10) should be on a horizontal line with the foot of the patient when the leg is lying horizontally on the pillow with the heel just clear of the bed. A convenient wood or iron bracket can easily be made by the carpenter or the splint maker.

3. Four block pulleys and suitable flexible cord. Application of the apparatus. The use of an anæsthetic is not required in children. In muscular adults we have found spinal anæsthesia to be of the greatest advantage.—(Lee-Veal)

1. The leg, having been prepared in the ordinary way is fitted with a spreader or block close to the sole of the foot by the method similar to that used in Buck's exten-

sion, although there are two important differences. (a) the strapping is not carried above the knee; (b) the spreader is provided with a pulley. A pattern of the spreader which we have found convenient is shown in Figure 12, but its essential feature is that it must be wide enough (5 inches) to deflect the strapping sufficiently to protect the malleoli from pressure. A light bandage over all from the roots of the toes to the knee, is ready.

2. The application of the pulleys (Fig. 9). First pulley *A* is tied to the overhead bar in such a position that a vertical dropping from it shall meet the leg well below the knee. Pulleys *B* and *D* are to be attached separately to the bar beyond the foot of the bed; pulley *C* is attached to the spreader.

3. The knee sling is now placed beneath the knee, which all this time has been lying comfortably on a pillow. The sling should be broad and soft—a soft rough bath towel suitably folded answers well. The ends of the sling are now securely tied together with a cord, which is then passed through the pulleys in the following manner: (a) up to pulley *A*; (b) to pulley *B* beyond the bed; (c) to pulley *C* on the spreader; (d) to pulley *D* (companion to *B*).

4. The surgeon now stands at the foot of the bed and slowly applies extension to the leg and then the weight is attached. He next takes a soft pillow and adjusts it comfortably beneath the thigh to prevent gravitational sagging at the site of the fracture. Care must be taken that the pillow is really soft, a common fault is to have a too hard and tightly stuffed pillow for this purpose. Next he looks to the heel. It must not be touching the bed, and he arranges another soft pillow beneath the leg and the tendon of Achilles to prevent it from doing so. Now the patient will be absolutely comfortable and rest of mind and body (including thigh muscles) will come to him. Finally careful measurements are taken. If the lower extremity of the anterior superior spine, the upper margin of the patella on either side.

The usual extension weight required for adults is 8 pounds; for infants and older children $\frac{1}{2}$ to 4 pounds. These weights it will be noticed, are doubled by the pulley arrangement nominally, but in fractures it would seem that there is considerable modification of the pull one way and another, and considerable latitude within the range of efficiency. The truth seems to be that a very moderate pull is adequate, provided it is fairly constant and comfortable. At the end of the third week Russell always seeks to reduce the weight. The surgeon's duty will be to take the measurements at least every morning and evening, and adjust the pillows beneath the thigh and leg so that there is no backward sagging at the site of fracture and the heel shall not be in contact with the bed. Very little is required of him, but while it is very little and very easy yet it is absolutely indispensable and must be faithfully given. The method is far from being fool proof and cannot and will not look after itself. The relation of the fragments should be checked by X-rays until reduction is obtained.

Again quoting Russell

In surveying what one has thus accomplished, we find the thigh muscles are being extended by the combination

of two forces. It is impossible to attain this by a single force acting in a straight line. The diagram (Fig. 11) will make evident the relative action of the forces employed. By constructing a parallelogram of forces it is seen that the resultant force will lie in the line of the thigh. Again, it will be noted that we have apparently taken no measures to secure and preserve good alignment; as bad alignment need never be seen in fractures treated in this way.

In his original report Russell states that experience has shown that the practice presents difficulties and pitfalls that have to be known and recognized and what at first appeared to be small details in the management of the cords and the pulleys turned out to possess unexpected possibilities, and he, in a very valuable way explains the causes of some of the poor results in this series of cases.

The most frequent of all errors, according to Russell, is that the foot is too high off the bed. The heel should be almost, but not quite, touching the bed. When the heel is too high a great part of the weight is employed in counteracting the weight of the limb which, of course, subtracts from the extension on the thigh muscles. Upon examining the parallelogram of forces one will clearly appreciate that the horizontal force is diminished as the heel is raised above the level of the bed. Russell feels that this has been a very common error in his application of the extension. Another influence upon the efficiency of the extension and the reduction of the overlapping is in the faulty direction of the upward pull on the knee. If Pulley *A* is wrongly placed nearer to the head of the bed than it should be the result is an upward pull which causes the horizontal pulley to pull against instead of co-operating with it. The position of pulley *A* should be such as to increase the effect of the extension and the change of its position frequently will make possible the complete reduction of the fragments, as in the Hodgen splint.

Another cause of failure to overcome shortening and restoration of the normal length of the bone is the use of too much weight. This is most frequently seen in children. If all the conditions which we have outlined, namely, position of the leg and foot in relation to the bed, the position of pulley *A* in relation to the knee joint, are such that the parallelogram of forces is as it should be, but the weight is excessive, we will find that the pelvis is pulled down on the injured side so that the patient lies very obliquely. When the pelvis is pulled downward, the limb is brought into a position of extreme abduction, when sagging of the fragments will occur and there will be shortening of the limb. (Fig. 189 of Russell's diagram, p. 500)

Finally, the most momentous, according to Russell, of the difficulties is the interposition of muscles, or the thrusting of a fragment through muscle, periosteum or other fibrous tissue and its incarceration in such a way that the end of the fragment cannot be apposed. It is this type of case which he thinks requires immediate operation and open reduction.

Russell claims that there is only one kind of faulty alignment or angulation that is likely to complicate fractures when treated in this way, and that is the gravitational backward sagging at the site of the fracture. This he says is due to the lack of the most ordinary care, namely, the omission of the pillow support to the under surface of the thigh beneath the fracture. In our cases we found that anterior angulation in the upper third has been almost as frequent as posterior angulation in the middle and lower thirds, and although Russell claims that outward or inward deviation is practically never seen, we find that it has occurred too frequently in our group of cases. Our experience has coincided with that of Ridgely and Bongardt, that it is necessary to use more weight than Russell or Ryan employ. Twelve pounds of weight in adults is the minimum.

CONCLUSIONS

From this statistical study of a group of 51 fractures of the femur treated in five different hospitals we feel that to obtain the maximum results from the Russell extension method in fractures of the femur one must

- 1 Apply the extension at the earliest possible moment after the receipt of the injury. After 3 hours the efficiency of the extension is opposed by the contraction of the muscles and the effectiveness of the extension decreases from hour to hour.

- 2 That the extension must be applied exactly as Russell has prescribed.

- 3 That the position of the patient and every detail of the apparatus must be meticulously readjusted as soon as it becomes disarranged. In young children and in restless individuals this may require almost an hourly inspection. This is not peculiar to the Russell extension method, which is really a suspension apparatus for such care is necessary in all methods of suspension

used in the treatment of fractures. In our experience premature removal of the extension has been one of the most serious faults. Although Russell feels that 4 weeks is more than enough, it has not been so in our group of cases, and Lund reports that the average time of extension in his cases was 12 weeks.

- 4 In speaking of the results in any method of treatment of fractures of the femur one must remember that the type of the fracture and the site of the fracture probably have more effect upon the anatomical restoration of the lesion than any method of treatment, and that the spiral, comminuted and oblique fractures in the intertrochanteric region or in the lower third of the femur always give the highest percentage of anatomical restoration. In a review of the literature of the Russell extension method it is surprising to find how many of the reported cases are of these favorable types.

SUMMARY

We have deliberately tried to avoid the expression of personal opinions in this report, but Dr Scudder tells us that in so doing we have failed to understand the object of the symposium. Therefore, for any criticism which we may receive for showing the same weakness that we have condemned in others Dr Scudder must take the blame.

We plan to continue the use of this method in the treatment of fractures of the femur in children beyond the age (4th to 6th year) when Bryant's vertical extension is not applicable, and in the favorable types of fractures in adults, i.e., the spiral, oblique comminuted, fractures occurring about the trochanters and in the middle and lower thirds of the femur. When we find that we are not succeeding we will quickly abandon this method for skeletal traction.

We will not attempt to use it in supracondylar fractures or in fractures of the upper third in muscular individuals.

The unfavorable results which we have obtained should, we feel, be credited to our failure to understand the principles of this method and to appreciate its limitations, and should not in any way be considered as condemning the Russell method of extension.

PATHOLOGICAL FRACTURES

E. L. ELIASON M.D. F.A.C.S., PHILADELPHIA

A PATHOLOGICAL fracture is one occurring from an malignant force acting upon a bone already weakened by disease. It is often spoken of incorrectly as being spontaneous in origin which implies sudden apparent causeless occurrence. Each so called spontaneous fracture however has a definite pathological basis. Each pathological fracture, depending upon its etiology varies as to its treatment and prognosis. Pathological fractures caused by benign or chronic conditions have a favorable prognosis, as a rule, while those due to malignancy and acute suppuration improperly treated, have an unfavorable one.

ETIOLOGY

Fracture statistics on the whole are deficient in complete analytical figures as to the relative causes of pathological fracture. Many cases originating as osteomyelitis, malignancy, etc. are overlooked or not reported because of the major interest of the etiological disease. Statistics relative to the incidence of disease in causing pathological fractures vary too with the size and type of hospitals. Speed states, for example, that at the Cook County Hospital he sees a large number of pathological fractures due to syphilis each year. His is a much higher figure than are those in smaller hospitals. Until a much larger number of these cases are available for study the knowledge of pathological fractures will be largely individualistic. Table I depicts a personally collected series from two hospitals. From this series it will be noted that bone tumors, benign and malignant, occupy the most important rôle in the production

of pathological fractures. At the same time it is unfortunate that the entire subject of bone tumors is one which is so controversial. Often the diagnosis must be made on the X-ray film, frequently with uncertainty. Indeed, the microscopic diagnosis of a questionable lesion, even in the hands of the best pathologists, is often a difficult one to make. Considerable strides, however are being made by the Committee on the Registry of Bone Sarcoma and others and today much more dependable figures are at hand than was the case when the writer presented this subject three years ago.¹

Speed finds malignant disease to be the most common cause of pathological fracture. This is indirectly confirmed by Christiansen, who, analyzing 1000 cases of bone tumors (disregarding fractures for the moment) found 918 or 91.8 per cent, were malignant (Waring). Judging from the personal series and from the observation of others, it is probably quite safe to say that bone tumors (malignant and benign) are the chief cause of pathological fracture, inflammatory changes second, nutritional disturbances third and neurotrophic changes fourth (Table I).

INCIDENCE OF BONE INVOLVEMENT

The incidence of pathological fracture is found to be greatest in the long bones connected with the trunk. The femur apparently suffers most. The humerus, tibia, and radius are the next most often fractured. The statistics of others approximate the personal ones given below.

In addition to the pure physical causes governing the bone involved, there is also an anatomico-pathological combination that makes for fracture-site incidence. Bone disease, which leads to pathological fracture, is found more often in the long bones than in the flat. The cancellous portions are frequently affected. Certain bone lesions tend to appear in the epiphyseal portions, rather than in the shaft, and consequently muscle action greatest near a joint, accentuates any force upon the potentially weak part.

In an incomplete, personal series, we find the bones most affected by pathological fracture to be as shown in Table II.

Bone metastasis from organic malignant disease may occur in flat or long bones. Flat bones are seldom subjected to trauma, except by direct

¹Eliason and Wright, Surg. Clinics N. America, vol. 2, 1125.

force while long bones are subject to direct and indirect forces the latter includes torsion and weight bearing as well as muscle play. One seldom sees a pathological fracture of the skull, ilium, bones of the face, carpus or tarsus.

In 13,055 fractures at the University Hospital up to August 1, 1932, the pathological incidence was 0.42 per cent.

AGE AND SEX

Pathological fracture occurs most often in the extremes of life and is determined largely by the disease which predisposes to the fracture. Nutritional defects as rickets and scurvy for example occur in youth likewise do bone cysts, giant cell tumors and osteitis fibrosa cystica. Sarcoma occurs in youth and early adult life more often than in the aged while carcinoma and neurotrophic or atrophic changes occur oftenest in late middle and advanced life. Acute infectious conditions occur in the first age period—1 to 20, whereas the chronic infections do not discriminate. These factors are more intimately referred to under their respective headings later. It may be well to note at this time that the prognosis, as a rule, is better in the younger patients than in the older ones. One might even say that the younger the patient and the earlier the disease (with but a few exceptions) the better the prognosis, and the older the patient or the longer the period of the disease the more dubious is the final hoped for result.

CLASSIFICATION

For reference purposes we have classified the fragility of bones under three major headings. Fragility is generally due to a local lesion, a systemic affection, or an hereditary diathesis.

Fragility due to local lesions—Bone cysts. The first under consideration is local cystic disease of bone. Under this heading are included osteitis fibrosa cystica (giant cell tumors, bone cysts, etc.) Blood or dentigerous cysts of the jaw, hydatid

Fig. 1. Left: Bone cyst or osteitis fibrosa cystica with fracture. Boy 8 years old. Insignificant fall. Roentgenogram shows typical lesion of a large bone cyst involving upper third of humerus, through which there has occurred a pathological fracture. The cyst has produced some thinning of the cortex but shows little tendency to expansion of the bone. The apparent trabeculations are evidently fractured portions of the thin bone shell. It begins as a medullary process, is osteolytic, usually single, does not invade the soft parts, and appears nearer the center of the diaphysis than does giant cell tumor, which hugs the epiphyseal area.

Fig. 2. Bone cyst with fracture and union. Same patient as in Figure 1, 3½ years after fracture. The X-ray shows the bone practically restored to normal. There is slight deformity and some increased thickening of the cortex with sclerosis at the site of the fracture. It is interesting to note that the healed fracture site is much farther down the shaft of the humerus than was the cyst 3½ years previously.

TABLE III—CLASSIFICATION

a. Fragility due to local lesion

1. Tumors

Benign—cysts (osteitis fibrosa cystica), enchondroma, thyroid.
Malignant—carcinoma, sarcoma, hypernephroma, endothelioma, multiple myeloma.

2. Infections

Acute—Calvé, Perthes, Krehler's, Kummell's, Kleinbock's and Ogood-Schlatter disease.
Chronic—tuberculosis, syphilis, Paget's.

3. Chemical and pressure causes.

b. Fragility due to general disease

1. Neuropathic.

2. Senility.

3. Osteoporosis of disease.

4. Osteomalacia, rickets, scurvy, etc.

5. Metabolic disturbances: diabetes, hyperparathyroidism.

c. Fragility due to hereditary disease

1. Osteogenesis imperfecta.

2. Osteosclerosis (marble bones).

3. Gaucher's splenomegaly.

and actinomycosis cysts and endochondromata of the phalanges and metacarpals are likewise included by some (French, Waring). Primary cysts will be considered first. Blood cysts are found in degenerating sarcoma (French). Hyda

Fig. 3A.

Fig. 3B.

Fig. 4.

Fig. 3. Metastatic carcinoma. Woman aged 52 years, primary lesion in the breast with generalized bone and visceral metastasis. Note the "decayed wood" appearance of the lesion before the fracture occurred. A, B shows the fracture 8 weeks after the insignificant trauma. Abundant callus is present and union is solid. Carcinoma of the breast causes frequent metastasis to the bones. It is a destructive process, usually beginning in the medullary canal and gradually increasing in size and destroying the cortex. It may ultimately weaken the shaft to allow pathological fracture. Carcinoma of the breast very frequently causes the osteolytic type of metastasis but it may cause the osteoplastic type.

Fig. 4. Osteogenic sarcoma. R. R. 38, female with a history of pain and swelling in the left lower thigh for 10 months. Osteomyelitis suspected because of the duration. A ray picture showed pathological fracture (diagnosis osteogenic sarcoma). A second picture taken 7 weeks later showed a moderate increase in the area of bone production about the pathological fracture with an increase in the soft tissue involvement about the lesion. Lesion apparently is progressing. No union. Microscopic diagnosis—sarcoma. Osteogenic sarcoma is a malignant disease usually occurring in the large bones, more frequently in the upper tibia and lower femur. It occurs between the ages of 10 and 30 years. It is usually an osteolytic process, beginning in the medullary canal or from the periosteum. It does not cause expansion of the bone but causes destruction. It erodes the surrounding tissues. When it is of periosteal origin, it very frequently causes a perpendicular striation of the new bone formation. The destruction of bone very frequently leads to pathological fracture.

thy cysts are uncommon in America but may be present in individuals who have lived in countries where the disease is prevalent (Russia, Armenia and the East). Such cysts affect the diaphyses of the long bones as a rule and convert the shaft into a thin walled tube which undergoes fracture as a result of slight trauma or muscular action. The existence of such cysts would hardly be suspected unless there were known hydatid disease elsewhere, especially in the liver. Cysts

of the jaw or dentigerous cysts may be the site of fracture. Landolt has pointed out that cysts due to echinococcus, cysticercus, actinomycosis or chronic osteomyelitis of bacterial origin may result in fracture. While fracture through simple cysts often cures such cysts (osteitis fibrosa cystica) fractures resulting from other types of cysts usually require open reduction and curettage. Treatment other than immobilization will depend on the treatment of the causative factor.

Fig 5 Hypernephroma. O K male 59 presenting an old pathological fracture of the left upper femur due to hypernephroma (metastatic). Patient operated upon 5 years previously for hypernephroma of the kidney. Three years later developed pain in the left hip and suffered a pathological fracture. One year later this had apparently united and caused no trouble. Patient admitted for a chordotomy to relieve pain incident to metastasis to the lumbar spine. X-ray examination of pelvis showed an old pathological fracture of the neck of the left femur, the neck of the femur being absent and no union apparent. Metastasis present involving upper femur, pelvis, and lumbar spine. Hypernephroma frequently causes bone metastases. The process is usually destructive and is very similar to that found in metastatic carcinoma. At times, however especially in the vertebrae it causes a condensing type of metastasis that may simulate prostatic carcinoma. Still at other times, there are areas of rarefaction and condensation showing a mixed type of cell in the metastatic process.

Fig 5

Fig 6B

Fig 7A

Fig 7B

Fig 6A.

Fig 6 Male, aged 32, with a history of neuralgic pains in his arm and shoulder for 18 months previous. On January 24, 1930, while steering a small car, he suddenly experienced a sharp pain and helplessness in his right arm. His physician diagnosed a fracture and the X-ray examination revealed the above described as a fracture through a bone cyst, myeloma or giant cell tumor. The X-ray picture, A, taken 3 months later shows extensive absorption of bone with no regeneration and no union of the fracture. The diagnosis now was sarcoma or Ewing's tumor or giant cell tumor. A cortical lesion diagnosed as bone cyst was discovered in the shaft of the ulna of the same limb, other bones of the skeleton were negative for tumor evidence. The lesion of the humerus was excised and a fibula transplant resulted in an excellent union. The roentgenogram, B, was taken 3 years later. The microscopic diagnosis was angio-endothelioma.

Fig 7 Multiple myeloma. The patient, a woman aged 45, was receiving X-ray treatment for multiple myeloma involving the skull. Pathological fracture of left femur followed few weeks later by fracture of right femur while being turned in bed. Union in both limbs. Patient subsequently had pathological fractures of spine, left humerus and left femur union occurring in all the long bone fractures. Succumbed to bronchopneumonia. Multiple myeloma is a malignant process, usually occurring in individuals between 50 and 60 years of age. It involves, more frequently the spine, ribs, and sternum. It is an osteolytic process, completely destroying the bone, beginning more or less in the medullary portions of the bone but may actually begin in the cortex. When it occurs in the spine, there is a widening and flattening of the vertebrae due to the loss of strain in the vertebrae, and stress and strain of the muscles. Pathological fractures occur very frequently. Multiple myeloma must be differentiated from metastatic carcinoma and parathyroid disease.

Fig. 8. Pathological fracture due to neglected osteomyelitis of 9 weeks duration. Diagnosed hematoma by the first physician. Abscess and fracture resulted. Condition spread to shaft and caused second fracture. Amputation eventually performed. X-ray picture shows a fracture of the surgical neck of the humerus through rarefied area which extend for a considerable distance down the medullary cavity of the bone. A low grade osteomyelitis showing but slight reaction to the infectious process. It is impossible to make an early X-ray diagnosis of acute osteomyelitis as it takes about two to 4 days to cause changes sufficient to justify one in making such a diagnosis. One should never wait for a positive X-ray report before making this diagnosis clinically.

Fig. 9. Acute osteomyelitis of femur with pathological fracture. Boy 13 years old. Hurt thigh is football. Incision revealed an abscess, X-ray examination, a periosteitis. Three weeks later present picture showed fracture. X-ray shows an oblique fracture at the junction of the middle and upper thirds of the right femur. The periosteum is elevated and thickened and there is an irregularity and mottling of the bone in the region of the fracture indicative of an acute osteomyelitis.

Fig. 10. Syphilitic osteomyelitis of clavicle with pathological fracture. Male, 3 years old. No injury. Fracture painless. Large spleen. Fifty neonovarian injections. Secured good union. X-ray examination shows generalized mottling of the involved portion of clavicle with increase in width of the bone due to the accompanying periosteitis with new bone formation. Osteomyelitis, due to syphilis, is slightly different from the usual osteomyelitis in that any periosteal proliferation assumes perpendicular striation whereas in ordinary osteomyelitis the periosteal proliferation is laid down parallel to the shaft. Syphilitic osteomyelitis, just as in the other type of osteomyelitis, is a proliferative and destructive process, which is always subject to fracture due to the weakened condition of the bone.

Fig. 11. A, Paget's disease with pathological fracture of femur. Female, 73 years old. While standing, leg gave way very slight discomfort. X-ray shows marked thickening of the cortex and irregular areas of bone density widening of the medullary canal and increase in the width of the bone trabeculae. X-ray of the skull will usually confirm this diagnosis. B, Shows union ten weeks after Russell traction treatment. Note the dense callus formation. X-ray shows pathological fracture in the right femur. Junction of the middle and lower third. Fragments in good position. Considerable bone callus at the site of fracture. The entire shaft shows diffuse irregular areas of increased bone density. Considerable thickening of cortex throughout. The appearance is that of Paget's disease.

Fig. 11 Sarcoid. J. C., 20 male, hospitalized for the treatment of malignant hypertension. No complaints referable to the hands and feet, though these were swollen, clinically suggesting gout. X-ray examination showed lesion involving the phalanges, metacarpals, and metatarsals chiefly rarefaction. Diagnosis of sarcoid made. Four months later re-examination of the hands showed an improvement in the appearance evidenced by a recalcification especially in those areas previously showing the greatest decalcification. Pathological fracture of the proximal

phalanx of the left ring finger evident at this time. Patient came to autopsy subsequently. Pathological examination of tissue removed from affected bones is typical of sarcoid. Sarcoid is a low grade tuberculous infection involving mainly the bones of the hand and feet, especially the phalanges. It may involve the cortex and medulla. It is necessary for this condition to be differentiated from Yaws or syringomyelia and possibly smallpox. The process is usually in the ends of the phalanges and invades the joints. It is a destructive process.

Fig. 13. Osteochondritis juvenalis femoris girl aged 11. In June began limping. In August an X-ray examination was reported negative. No pain. In December 4 months later while walking on a level pavement, the limb gave way with resultant slight pain. X-ray at this time revealed an epiphyseal separation with diaphyseal bone vacuoliza-

tion, A. Left Diagnosis osteochondritis. Roentgenogram B taken 1 year later shows perfect union as well as recovery from the inflammatory condition. Note Examination of the first (August) X-ray film reported negative revealed a "slipping epiphysis with vacuolization or moth-eaten appearance and absorption of the diaphyseal border"

Fig. 4. Giant cell tumor of the lower radius. Male, 49 years old, while receiving radiotherapy had to be splinted indefinitely. Note atrophy of diaphysis of phalanges. Had ulnar neuritis from pressure. X-ray picture shows a large tumor involving the lower portion of the radius. It has the characteristic trabeculated or soap bubble appearance of giant cell tumor. There has been a gradual expansion of the cortex which is everywhere intact. Note the abruptness with which the tumor stops in its upper portion, thus indicating its benign character. There is a fracture through the head of the fifth metacarpal, evidently from atrophy of diaphysis. Further note the pressure absorption in the area opposite the radial tumor.

Fig. 5. Giant cell tumor. Clinical and X-ray impression was giant cell tumor. This was confirmed at operation 3 months later and the cavity was filled with bone chips. Two years ago the patient fell while bathing and injured the lower left femur. X-ray examination showed a fracture, pathological in nature, through the inner condyle of the lower left femur. Giant cell tumor is usually single, but may be multiple and is a benign lesion. It occurs in the ends of the diaphyses and in the epiphyses, most often between the ages of 20 and 30 years. The lower end of the radius, tibia, and fibula are the usual sites of this lesion. It is a medullary osteolytic lesion which grows gradually and expands the bone. It is frequently found entirely by accident secondary to a pathological fracture. The process expands the cortex and does not invade the soft tissues.

Chondroma or enchondroma. Chondromatous of bone are benign though those connected with soft tissues may develop into chondrosarcomata. They usually form at an epiphyseal line and extend distally—expanding widely as they grow (French). The phalanges are the commonest site but the lower end of the femur, the great trochanter and upper end of the humerus, may also be affected. Though usually found in the long bones, Babcock states that they may locate about the hip joint, the neck of the scapula and about the glenoid fossa. They are slow in growth, frequently multiple, and may be peripheral or central. Unless excised, the bone is gradually destroyed and a pathological fracture results. There is no pre-

Fig. 6. Pathological fractures of the neck of both femurs due to Charcot's joints. Male aged 55 years. Slightly painful swelling for one year. No trauma. Walking on arrival. X-ray shows evidence of an old fracture of the neck of each femur with marked upward displacement of the shaft. The acetabula are shallow and rarefied. The head of each femur is flattened and also shows rarefaction. These fractures never unite. The X-ray appearance of Charcot's joint is one in which there are considerable hypertrophic and atrophic changes with loose body formation. The destructive changes and hypertrophic changes are out of proportion to the discomfort of the patient. This process, especially when it involves the hip joint leads to a pathological fracture of the neck of the femur.

dilection as to sex or age except that the lesion does not usually occur after middle life. When the condition is brought to the attention of a surgeon only after a pathological fracture has occurred, it is necessary in the larger long bones to excise the enchondroma prior to immobilization before union will take place. Shortening may result in small bones, as the phalanges.

Osteitis fibrosa cystica. By far the greatest number of pathological fractures due to cystic disease of bone is the result of osteitis fibrosa cystica. About this term and several others connoting the same condition (osteitis fibrosa, fibrous cysts, bone cysts, cystic disease of bone, fibro-cystic disease of bones, von Recklinghausen's disease, etc.) lies a certain amount of confusion. Geschickter and Copeland have recently clarified the situation somewhat. They have reviewed 400 cases of bone tumors of the giant cell group, including giant cell tumor, osteitis fibrosa, solitary bone cyst and are of the opinion that the three are one and the same condition in different stages and all due to trauma. The condition occurs most often in youth and at the metaphyseal regions of the long bones, chiefly the humerus, femur, tibia, and radius. A fracture from slight violence is frequently the first intimation of trouble. The X-ray findings are characteristic (Fig. 7). The fracture is not very painful is often

Fig. 17 A, United pathological fracture of neck of femur due to osteomalacia. Female aged 23 years. Fractured hip when 6 years old and femur when 19 years of age. Concave cortex is thick. X-ray film shows an old united fracture of the neck of the femur with consequent deformity of the hip joint. There is marked decrease in density and a loss of the normal bone trabeculations as compared with the opposite femur. B The shaft distal to the trochanters shows bowing with thickening of the cortex on its entire inner aspect evidently the result of faulty weight bearing in an osteoporotic bone.

Fig. 17 A

Fig. 17 B

Fig. 18. Rachitis. C. P. male child, 29 months old, with a pathological fracture of the shaft of the left femur due to rickets. Normal delivery bottle fed baby no cod liver oil or viosterol. Walking delayed until age of 2 because of a club-foot, present at birth. Injured left limb from trivial trauma at play. X-ray film showed typical signs of rickets. Treated by suspension, Bryant's method. Good union in 1 month. X-ray film on discharge showed evidence of healing rickets in both lower extremities. This is a deficiency disease of the bone. The process is osteolytic in type involves multiple bones. It is usually seen in children after the age of 4 months and is supposed to be due to vitamin deficiency. It is a benign process which heals by regulation of the diet and vitamins. When fractures occur they usually occur near the epiphyseal line where the (Rickets) bone is weakest due to the osteoid tissue. The X-ray appearances in a typical active case shows disappearance of the center of ossification in the epiphyses, widening and cupping of the diaphyseal end which expands with the enlarged epiphyses. Osteoid zone at the ends of the diaphyses and disappearance of the zone of temporary calcification.

Fig. 18.

Fig. 19.

Fig. 19. Hyperparathyroidism. The photograph is that of the lower extremity of a young man, from whom on three occasions a parathyroid adenoma was removed. The patient has had countless fractures over his entire skeleton. The X-ray film shows the pronounced widespread decalcification and oftentimes a pathological fracture. The patient did not have a recent fracture at the time of this exposure.

Fig. 20A

Fig. 20B

Fig. 20 A Multiple pathological fractures of right femur and bones of both legs due to osteogenesis imperfecta. A month old girl one of twins. Both suffered similarly. X-ray film shows marked deformity of both lower extremities due to multiple fractures of the femora and tibiae. All the bones show the generalized decrease in bone density characteristic of osteogenesis imperfecta. It is an osteolytic process evidenced by decreased density of the bones, thinning of the cortex, and multiple fractures. The fractures unite with considerable external callus formation. These twins had been on orange juice and milk under the supervision of children clinic previous to admission with the fractures. In the hospital the treatment consisted of orange juice, cod liver oil, heliotherapy and traction. B. Sixteen months after intensive treatment. Both twins had no further fracture for 3½ years. X-ray film shows practically normal lower extremities. The deformities have disappeared, there is little or no evidence of the previous fractures. Not the marked increase in bone density

Fig. 2

Fig. 2. Gaucher's disease. Female aged 9 years, was observed over a period of 4 years during which five pathological fractures were treated. At the age of 5 child was hospitalized with a fracture of the upper right tibia and of the left femur, satisfactory union. Tentative X-ray diagnosis, Gaucher's disease. At the age of 6 years, had fracture of neck of right femur, satisfactory union. At the age of 7 child again had pathological fracture of the neck of the right femur while walking. Union satisfactory but considerable lateral bowing followed this injury. Child was treated by diet and rest during this period. Fracture of the left humerus at age of 8, good union. At present there is considerable anterior bowing of left humerus and the right leg which is shorter than the left shows marked anterior bowing of the femur. X-ray studies of the skull show diffuse areas of rarefaction and areas of increased density the lesion increasing steadily. The blood calcium is 0.5 milligrams.

communited although with little overriding, and union occurs usually with a resultant cure of the cystic condition. Follow up reports have shown, however, that at least in some cases of fracture, irradiation has given the most lasting cures, probably because of parts of the cyst having escaped the curative trauma of the fracture.

Metastatic carcinoma (Fig. 3 A and B). Carcinoma of bone is metastatic, or the result of invasion from an overlying tumor. It is well known that carcinoma, especially of the breast tends to produce bone metastases. Carcinoma of the stomach may also give rise to secondary deposits in the bones. Waring found that metastasis to bones occurred in 53 cases (4.6 per cent)

of 1,144 autopsies upon cancerous patients. Of the 53 cases, 34 (64 per cent) were carcinoma of the breast primarily. The first signs of malignant disease may be osteoporosis, erosion, and fracture although pain frequently calls attention to its condition. Usually more than one bone is involved. Unlike sarcoma, the bone lesion is rarely large enough to command attention and the growth is slow. A moth-eaten or "decayed wood" appearance with a compensatory periosteitis results. The common sites for metastases, with fracture are the femur, humerus, ribs, and sternum. Handley (Speed) in 329 cases of carcinoma of bone, due to metastasis from carcinoma of the breast found the bone incidence as follows

	Per cent
Sternum	9.0
Ribs	8.0
Femur	4.2
Spine	3.6
Humerus	2.7
Cranial bones	2.7

Handley states that in carcinoma union is the rule. Pancoast estimates that union occurs in probably 40 per cent of these cases with or without radiation.

The prognosis, of course, is very poor, as with other malignant bone affections. The local lesion causing the fracture is only an incidental part of the generalized malignancy. The prognosis is similar to that in sarcoma of which Ewing remarks "The surgical treatment of bone tumors is highly unsatisfactory. Amputation is seldom indicated from a curative point of view as it may be indicated in early cases of sarcoma. It may be performed for the patient's benefit to shorten his hospitalization and to free him from malodorous dressings disability and pain."

Sarcoma (Fig. 4) Sarcoma of bone is usually primary and of the osteogenic type. Pathological fractures occur and union after fractures is possible, but rare (Babcock). Waring has seen union occur, but Bloodgood has seen only one case in which union occurred and one other questionable case. Pancoast has no case of union in his files. Pfahler recalls no case with resultant union. Meyerding (see Waring) analyzing 109 cases of sarcoma involving bone found the different types to be as follows

	Cases
Mixed celled sarcoma	51
Osteosarcoma	19
Chondrosarcoma	17
Round cell	14
Fibrosarcoma	8
	109

Waring classified sarcoma of bones into periosteal sarcoma and endosteal or central sarcoma. The first should not be confused with parosteal sarcoma which is sometimes termed periosseous fibrosarcoma. This latter is not a true bone tumor, but lies adjacent to bone and may by pressure affect bone without invading it.

Periosteal sarcoma is more common than endosteal. The metaphyses of long bones is the commonest site. Seventy two per cent (Babcock) involve the lower extremity and 82 per cent of these occur near the knee. The shoulder girdle is next in frequency. The humerus is usually attacked above the deltoid tubercle the scapula in its glenoid cavity or spine and the clavicle

in its outer one half. Other bones may be involved, but are seldom fractured. The fact that the lower epiphyseal end of the femur and upper epiphysis of the tibia are the last to ossify may explain the predilection for this area (Babcock).

Trauma is said to precede 50 per cent of cases of osteogenic sarcoma and the tumor to develop within 1 month after injury in 30 per cent of cases. The bones concerned in the formation of the knee joint and shoulder girdle likewise receive a large share of trauma in the young among whom it most often appears. Strangely enough the lower end of the radius (though often injured) is rarely affected and there is no record of the distal end of the ulna ever being involved.

Males are affected in the proportion of 3 to 1 though females predominate during the first decade of life. Sarcoma of bone occurs chiefly in childhood before the age of 20 years and is rather rare after the age of 40, except where it is secondary to Paget's disease. According to Codman (Babcock) 14 per cent of all patients with Paget's disease die of osteogenic sarcoma.

The X-ray picture of the lesion is generally characteristic. There is a fusiform swelling or spindle contour at the end of the bone. The joint or epiphysis is not invaded. The periosteum becomes markedly elevated with a thickened 'lippling' of its margin. In 18 per cent there may be noted fanlike radiations which give it the so-called 'sun rays' appearance. Expansion of the shaft rarely takes place. The spindle mass is caused by penetration of the bone by the tumor and the formation of a mass around the shaft.

Treatment is more hopeless when a pathological fracture occurs than otherwise. By the time the surgeon sees the case the resulting trauma to the tissues has opened the blood and lymphatic vessels thus predisposing to metastasis. The mixed toxins of Coley, irradiation and amputation, are reported to have cured some cases of sarcoma but rarely so when fracture occurs. Cases thought to be cured of their local lesion by irradiation generally die later from metastasis. By the time the bone is involved sufficiently to result in fracture, dissemination has either begun or occurs with the injury to the tissue at the time of fracture.

The writer has successfully treated 2 cases by amputation. One was in the distal portion of the femur and one in the tibia. Both diagnoses were proved by the microscope. One case is alive at the end of 18 years and the other at the termination of 12 years. There is no doubt that amputation is of value only when the condition has just begun and when it is distally located. A high amputation

may then be successful. Coley has recently reported 3 cases of the endothelioma type with apparently successful cures by operation and the use of Coley's fluid. One patient was well 3 years later and the second 4½ years after. Coley and Sharp state that fracture through osteogenic sarcoma shortens life expectancy 60 per cent.

Statistics show (Ewing) that nearly all osteogenic sarcomata prove fatal and while recovery seems to have occurred in rare cases "this forlorn outcome is the meager fruit of large numbers of useless amputations." However amputation in many instances has its advantages. It shortens the hospitalization of the patient. It relieves the patient of an incapacitating, often painful frequently ulcerating, foul smelling lesion requiring painful dressings. Furthermore, after such operations patients have been known to live with comparative comfort for many months despite the presence of visceral metastasis (lungs) at the time of operation.

Endothelioma (Figs. 5 A and B) An endothelioma is a tumor originating from endothelium and resembling both sarcoma and carcinoma. It forms about 7 per cent (Babcock) of the sarcomata of bone.

It affects the long bones more often than the flat. The most common sites are the tibia, fibula, humerus, ulna and the femur. Other small bones of the feet, ribs, vertebrae etc. may be affected. In the latter locations it must be differentiated from multiple myelomata. The tumor widely involves the shaft of the long bones or starts in multiple areas. The tissue itself is soft mushy and whitish gray. While it destroys bone a regenerative process likewise takes place at the periosteal borders. Various layers are formed in the course of time giving the roentgenogram the peculiar appearance termed 'onion layer' (Babcock).

The disease frequently follows trauma and is usually one of youth, 50 per cent of the cases occurring before the age of 15 years. Because of the pain, limitation of motion, slight fever and leucocytosis, it may be mistaken for osteomyelitis. The joint is seldom involved and pathological fracture occurs late.

Metastasis via the blood or lymphatic stream occurs with great rapidity in the lungs, skull, various bones, liver, spleen, and regional lymph nodes.

The prognosis is very poor as death generally occurs in from 6 months to 2 years. The disease is very sensitive to irradiation.

Treatment consists of immobilization and possibly irradiation. Union may occur as temporary

improvement or retrogression takes place with radiotherapy. If the condition occurs in an extremity and is recognized before metastasis takes place, amputation in our opinion should be done.

Hypernephroma—metastatic (Fig. 6) Hypernephroma is now considered to be a malignant adenoma or adenoid polyp of the kidney. It occurs generally in young girls and in adult men. The condition is extremely malignant and metastasis occurs via the blood stream to the liver, lungs, and bones. The bones most often affected are the skull, humerus, and femur. Cases have been recently reported by Mazzini, MacKechnie, and by Broder. Rapid recurrence generally follows extirpation of the original tumor. Excision or amputation, when pathological fracture occurs, offers no hope of cure. Death usually occurs in from 2 months to 3 years. Radiotherapy and Coley's fluid may be tried. The prognosis is more grave than that of a pathological fracture due to sarcoma.

Thyroid—metastatic. Bloodgood states that the majority of these lesions are metastases from a malignant adenoma of the thyroid gland although other authorities consider the condition non-malignant. Blumer has analyzed the reported cases and finds that 38 per cent occur in the bones of the face and cranium, 16 per cent in the vertebrae, and only 15 per cent in the long bones—hence fracture is comparatively rare.

Multiple myeloma (Figs. 7 A and B) Myelomata, in comparison with the single benign myeloma of bone, are multiple, malignant, and subject to metastases. Fortunately the condition is rare (Waring). The bones most commonly affected are the ribs, sternum, vertebrae, cranium, ilium, and (very rarely) the long bones of the upper extremity. Often the first symptom is pain in one of the areas most affected. As the disease progresses metastases take place in other bones. When the spinal column is affected the pressure on the cord may resemble that of a spinal cord tumor. Pathological fracture is seldom seen as the flat bones are oftenest involved. Anemia is sometimes present. Males, generally between 4 and 60 years of age, are most likely to be affected. The prognosis is very poor as death usually occurs in a few months. Surgery or radiation is of little value because of the widespread metastases. Treatment is directed to immobilization, sedatives, and attending complications. Union does occur proved by the case illustrated in Figure 7.

Infections. The infectious diseases of bone leading to pathological fracture are subdivided into the acute and chronic.

Acute pyogenic infections (Fig 8) Acute osteomyelitis may form a localized abscess involving a large portion of a bone and lead to fracture. As a rule however more extensive destruction takes place with a resultant periosteitis, necrosis, sequestrum formation, and pathological fracture. The first two decades of life (males particularly) are probably more often affected than any other. The condition is sometimes erroneously diagnosed rheumatism subdeltoid bursitis, etc. This is understandable when X rays taken at the beginning of pain may be negative for bony pathology. The treatment is essentially that of an infected compound fracture, namely adequate drainage plus immobilization. When such cases come to the surgeon early the prognosis is good. In neglected cases, non union may occur, particularly when improper splinting has been applied. Union is the rule in pathological fractures due to acute osteomyelitis where early drainage has been secured. Excessive callus is often seen.

Chronic infections—syphilis (Fig 10) Syphilitic disease of bone *per se* is seldom a cause of pathological fracture. Such fractures though, occur fairly often in patients with cerebrospinal syphilis.

The local affection of bones is generally a periosteitis which results in a thickened cortex and osteosclerosis. Nodular swellings may occur as in saber shin. Subperiosteal gummata may destroy bone and weaken it sufficiently to cause pathological fracture. This is particularly true where an ulceration or infection is engrafted upon a secondary osteomyelitis. Constant has reported pathological fractures of the femur due to syphilitic osteomyelitis. Sihol has reported a similar case with recurrence. Achard and Walter have made a study of clavicular fractures in syphilis. Figure 10 shows a personal case.

Chronic infections—tuberculous osteomyelitis These affections are often seen in the phalangeal tarsal, and carpal bones of children as strumous dactylitis. There is a localized fusiform swelling of a phalanx or metacarpal bone, caused by a tuberculous caseous process that breaks through the cortex. In adults, a diffuse thickening from periosteitis and the formation of a central sequestrum occurs. With necrosis, a pathological fracture may take place.

The disease attacks long bones in the region of the epiphyses. The short long bones are usually affected nearer the shaft center. The femur, tibia, humerus, and bones of the forearm are the ones most often fractured. The ribs may be invaded by extension. Lenormant has reported pathological fractures of ribs in tuberculous osteitis.

In America the condition is on the wane, due no doubt to better milk laws. Innumerable cases of tuberculous osteomyelitis still occur in Turkey, the Balkans, and southern Russia, where the majority of cows are affected with bovine tuberculosis. The condition occurred most often before the age of eighteen.

Chronic infections—osteitis tuberculosa cystica multiplex (sarcoid) (Fig 11 A and B) In this disease tubercle bacillus is the etiological factor. It manifests itself in typical skin lesions or in typical bone lesions, or in both. All the lesions are painless. Emaciation and weakness are pronounced. The bone lesions are limited to the hands and feet, chiefly in the phalanges but they do occur in the metatarsals and metacarpals. The X ray changes consist of a slowly progressing alteration in the trabecular formation of the bone, followed by actual bone destruction, either central or cortical or both. In another type the lesions begin as punched out areas sometimes extending entirely through the phalanges. Complete destruction is most likely to occur in the terminal phalanges. The disease is a chronic one and the tubercle bacillus is not always found nor is caseation ever present.

Sufficient information is wanting upon which to make any statement as to the incidence of union in pathological fracture in this condition.

Chronic infections—Paget's disease (Fig 12A and B) Paget's disease is a condition of unknown origin and very likely due to an infectious process. It is a chronic, progressive, and symmetrical disease affecting chiefly the long bones, skull and spine. Early hyperemia, bone absorption and softening take place. These changes are followed by bending, thickening, sclerosis and a tendency to sarcomatous change.

According to Babcock the marrow first becomes vascular and the bone, rarefied and partially decalcified bends under pressure. Later excessive bone formation occurs with calcification and sclerosis. It is during this latter stage that pathological fracture is most apt to occur.

The curved legs, bowed knees, kyphotic spine, and anthropoid carriage attest the progress of this incurable disease. The femur and humerus are the bones most liable to fracture. The fracture line itself is characteristic, and generally is clear cut, transverse or of the "step type." Union occurs but is slow and prolonged immobilization is required. Excessive callus is the rule.

The progress is favorable as far as eventual union is concerned, but it is grave inasmuch as 14 per cent (Codman) of the patients die of a secondary osteogenic sarcoma. "If there were

non union of a fracture in a bone, evidently an example of Paget's disease. I should be suspicious of secondary sarcoma and amputate at once (Bloodgood). The presence of osteogenic sarcoma in later life is almost presumptive evidence (Babcock) of Paget's disease. Recurrent fractures are apt to follow.

During the progress of the general disease the skull becomes extremely thick and the intracranial space decreases. As a result, severe headache, cerebral pressure symptoms and mental deterioration take place. In the elderly, softening of the fractured ends may develop into sarcoma.

No cure for Paget's disease has been discovered. Parathyroid thyroid calcium therapy and Ir-radiation have been tried with indifferent and variable results. As the condition is often ushered in with a slight fever, dull aching pains, and hyperplasia of bones it is not without hope that some one may yet discover an infectious agent to be its cause and a subsequent cure result.

Fragility due to infection of epiphyseal areas (Fig. 8 A and B). The following conditions fall into this category:

Osteochondritis deformans juvenilis comes results in pathological separation of the epiphysis of the head of the femur (slipping epiphysis) and produces deformity and shortening unless detected and treated early. Immobilization in a Whitman cast and prevention of too early weight bearing afterward suffice for a cure. The prognosis is good.

The slipping tibial tubercle described by Osgood and Schlatter and seen most often in rapidly growing male adolescents, might well be grouped here. The condition is readily recognized if one is on the look out for it.

Kochler's disease, Knemmel's disease and Keinboch's disease might be classed as pathological fractures if we consider trauma as the etiologic factor.

Local pressure (Fig. 14). Local pressure on bone may lead to necrosis and subsequent pathological fracture. Some of these causes are: Pressure upon a contiguous tumor, pressure upon ribs, sternum, or vertebrae, pressure from a tight encircling wire or metallic band. The treatment consists of removal of the cause when such is possible. A personal case is recorded in which the fracture was due to pressure necrosis resulting from the application of a Parham-Martin band in another hospital. Garr has reported a similar case. Kilgore and Chamberlain have reported "fibrosarcoma of soft parts causing pathological fracture of the femur and giving an X-ray ap-

pearance of periosteal sarcoma." A double fracture of the mandible predisposed by an impacted molar has been described by Crich.

Fragility due to general disease *Neuropathic* (Fig. 16). There are certain diseases affecting the central nervous system in which pathological fractures occur. The most common are tabes dorsalis, paresis, syringomelia, spina bifida, hemiplegia, and infantile paralysis.

The exact cause of predisposition to fractures in these conditions is not as yet known. No doubt there are several. It is known that injury to a nerve supplying a part causes trophic disturbances. An atrophic bone readily fractures. Alhson and Brooks have shown that bone atrophy of disuse is a quantitative rather than a qualitative chemical change. The chemical constituents of the bone making for strength and elasticity are deficient. The bone is fragile and it breaks easily. Other accessory factors, such as loss of pain and sensation, weak, atrophic musculature and hypoplasia of bone may play a part.

Neuropathic—tabes dorsalis and paresis. The greatest number of pathological fractures in syphilitic patients occurs in tabetics and in paresis. According to Speed "the nervous system also has on bone an influence which predisposes to fractures. Neurotrophic influences in instances, in paralyzes, and particularly in tabes must be considered. In the Cook County Hospital there are each year 12 to 15 cases of pathological fracture or fracture dislocation in tabetics. They are usually near the joints, accompanied by much bone change of a rarefying or hypertrophic character of typical Charcot joints, and are quite painless. Some patients present three to five fractures at the same time."

Cotton is of the belief that "fractures in tabetics are hardly spontaneous; they depend on inordinate but powerful muscle action (as in fractures due to feats of strength) for contrary to the common statement, the bones of tabetics are apt to be heavy and hard rather than atrophic."

Pathological fractures in paresis usually occur late in the disease when these patients are bedridden and their paralyzed extremities are in an atrophic stage. False claims (French) of rough handling by attendants may be made. The femur is probably most often affected, occasionally the clavicle may also be affected. The diagnosis rests partly upon the history, physical findings, blood or spinal Wassermann test, and the X-ray picture.

Treatment consists of proper immobilization, active antisyphilitic treatment, including large doses of iodides (Babcock) and drainage or dressings in cases of a "mixed infection" osteomyelitis.

The prognosis is good as a whole particularly where the disease is local. Speed agrees that most tabetics even with Charcot's joints, heal though with deformed, but nevertheless functioning, joints.

Neuropathic—syringomelia. Fractures in this condition are usually observed in the upper extremities while tabes which simulates it somewhat generally causes fractures in the lower limbs. The patient may not recall any traumatic cause, being insensible to pain. Schultz reports a baker who fractured his arm during ordinary kneading of dough. The patient felt no pain, but the crepitation and shape of his arm attracted his attention. A patient of Bernhard's also sustained a fracture of the ulna while at work but continued to break stones. The next day he even earned water before consulting a doctor. Schlesinger reports a woman who heard a crackling sound while turning a bed cover. She then found that she had fractured both bones of her forearm. Schultz finds curiously that the right side is seldom affected and the lower extremities rarely.

The fractures are apt to occur only in the late stages of syringomelia. Normally they heal quite rapidly or may require a long time and pseudoarthroses may form. The callus may be normal in amount or superfluous. It is the opinion of Schultz that because of the loss of pain and muscle sense the patient may not be aware that he is subjecting his muscles to any excessive strain. Similar instances are seen in normal individuals performing feats of strength. Recent articles regarding pathological fractures occurring in this condition have been published by Koch and others.

Neuropathic—spina bifida. Pathological fractures in the lower extremity have been noted in cases of spina bifida. Its occurrence is not common. Its cause is attributed to bone atrophy as a result of the involvement of the lower spinal nerves in the meningocele. It may, however, be due to atrophy of disuse where the lower limbs are paralyzed. Where the neurotrophic condition has affected the growth of the bone, hypoplasia of bone rather than atrophy may occur. An 8 year old boy under our present care illustrates this.

Neuropathic—hemiplegia. Fractures due to bone atrophy and disuse usually occur in elderly hemiplegics. Often they are bedridden, though a defensive movement in an ambulatory case may result in fractures. The site of fracture is usually the anatomical neck or upper shaft of the femur. Occasionally the humerus suffers. Experience has taught us that the usual treatment of the past

(plaster cast) is often inadvisable. As a general rule, the Russell apparatus is the most satisfactory treatment for fractures of the femur. It is best to keep the patient in semi Fowler position.

The reasons that have led us to adopt this form of treatment are. The frequent occurrence of hypostatic congestion and pneumonia, and decubitus in cases treated with a plaster cast, difficult nursing care delayed or non union in many cases, regardless of the form of immobilization and finally economical and functional considerations. The patient is elderly and bedridden. The extremity is paralyzed and functionless, with or without union. Why then restore bony alignment in a paralyzed extremity at the cost of life from complications? The time will come when useless limbs will be amputated.

Neuropathic—infantile paralysis. In either in infantile spinal paralysis or the cerebral paralysis of children the growth of the bones in the affected extremity does not keep pace with the normal side. Bone hypoplasia and a retardation of bone growth may accompany bony and muscular atrophy. Willard mentions bone atrophy following poliomyelitis. Hassen and his associates have reported a number of cases. The question is unsettled as to whether the lack of regenerative power of bone in cases of paralysis is due to disuse or trophic disturbances. Putru found experimentally that nerve trunk lesions have no effect on the formation of callus. Others have reported differently. Allison and Brooks show the effects of disuse in the production of bone atrophy. Tumpeet and McNeely have recently reported 2 cases of fractures in poliomyelitis.

Delayed union and refractures are apt to occur.

Osteoporosis of disuse. Osteoporosis of disuse is essentially bone atrophy due to prolonged immobilization or insufficient motion in a part. Bone stability is apparently due to proper nutrition supplied by an adequate circulation or tissue respiration. When either of the latter is interfered with, decalcification results. Hypomotility decreases tissue respiration. This condition is frequently observed in extremities that have been overimmobilized or have not functioned because of paralysis. It is encountered in the extremities of hemiplegics, infantile paralytics, deltoid musculospiral, and circumflex paralysis etc.

The prognosis is good if there is no accompanying nerve paralysis, though in the aged senile changes, etc. must be remembered. As a rule, early mobilization, diathermy, baking, massage and passive motions bring a good result. An unusual case is that of a young man (distal end of fifth metacarpal) who developed a pathological

fracture of his fifth metacarpal as a result of prolonged immobilization of the wrist (and possibly from nerve pressure) while being given radiotherapy for a giant cell tumor of the lower end of the radius.

Osteomalacia. (Fig 8 A and B) Osteomalacia is an abnormal softening of the skeletal system. It affects adults primarily. So called juvenile osteomalacia as a rule is osteogenesis imperfecta, with which it is often confused. In America, osteomalacia occurs most often in lactating women and is fairly common among those (Italian and Austrian) who are often pregnant, have a poor diet, and suckle their young for 1 to 2 years believing pregnancy can be avoided thereby.

War and famine osteomalacia was observed very often among the Central Powers during the great war. Maxwell (Peking, China) claims that osteomalacia is seen more often in India, Kashmir and Northern China than in any other countries. In the latter place there are at least 40,000 to 50,000 cases, mostly found in the uplands of Shansi and Shensi, in the middle belt of Kansu and in Manchuria. It is occasionally found in isolated cases all over the Republic of China. Hunger or starvation osteomalacia, as it is also called, is due to a long continued improperly balanced diet. Lack of fresh foods containing vitamins and absorbable calcium has been found to be the cause. Recently we have observed this condition in a 38 year old female dietitian who, through voluntary dietary restriction to make herself thin, so succeeded that her tissues were those of a case of rickets. She was nearly 6 feet tall and weighed only 100 pounds. She was devoid of subcutaneous adipose tissue and the osseous system was quite porous. The fracture sustained was an intracapsular one of the femur with practically no pain. She has made an excellent recovery through immobilization, diet, and ergosterol.

The condition when due to famine affects naturally both sexes and all ages. The diagnosis is generally made by X-ray. When the disease has progressed for a long time before fracture bowing of the femora and pelvic deformity may be physically observable. The roentgenogram of the fractured and other bones reveals osteoporosis. The degree of bone porosity varies with the stage or severity of the disease. The bones are lacking in calcium and the blood content of calcium may be as low as 5 to 6 milligrams (Mills and Feng). Bending of the long bones is often noted. It is due to weight bearing and bowstring muscle action.

The prognosis is favorable although union may be delayed if metabolic needs are not appreciated

and refracture may occur for the same reason. In addition to immobilization, treatment should be directed to the causative factor. In the case of *famine osteomalacia*, a normal diet should immediately be given. It should be reinforced by articles that can quickly make up the deficient bone regeneration. Food products rich in vitamins C and D should be given. These consist of milk, codliver oil, egg yolk, orange and lemon juice, apples, and bananas.

Administration of parathyroid (Collip) may be given a trial. New calcium, easily absorbable, must be supplied by diet. Codliver oil, viosterol, ergosterol, ultraviolet rays, or sunshine, aid in better calcium absorption and deposition. In lactating or pregnant women it may be advisable to terminate lactation or pregnancy and immediately institute the calcium-increasing treatment outlined. The fetus in osteomalacia suffers with the mother. Osteoporosis and a diminished amount of calcium in the blood and umbilical cord are generally found. Maxwell, without terminating pregnancy has been able to treat an expectant mother, cure her during gestation and normally deliver her of a normal child. He uses diet, codliver oil, and irradiated ergosterol.

Cases due to starvation or underfeeding have been reported by Simon, Steiner, Hahn and by Asner.

Rickets (Fig 18) Rickets is observed most often in infants, but it may persist to adolescence. It is due to the lack of vitamin D. Negro children are probably most often affected. It is a hypovitaminosis due to a poor diet on the part of the mother or an improper baby formula. In infants the fontanelles delay in closing. A rachitic rosary is often present. The epiphysis and joints are enlarged. Curving of the long bones results. The bones are deficient in calcium and phosphorus and often contain an abnormal proportionate amount of magnesium and sulphur. The bones are fragile because they are soft. Fractures are similar to those in osteogenesis imperfecta. The X-ray reveals, however, cupped epiphysis in addition to bone porosity. Multiple fractures and recurrent fractures occur when the condition is not recognized or vigorously treated. The prognosis is good under proper treatment. Excessive callus is often the rule.

The treatment consists of proper immobilization and attention to diet and vitamin requirements. If the baby is still nursing it should be taken from the breast and placed upon a proper formula. Orange juice, codliver oil, ergosterol, viosterol, etc. should be added. Schilowetz has demonstrated that avitaminosis retards the for

mation of callus. When available sunshine and ultraviolet irradiation are extremely beneficial. Scurvy may attend the condition as it did a recent one of our own.

Scurbulus Scurvy may occur at any age and in either sex. It is a hypovitaminosis and occurs when the diet is lacking in vitamin C. Imperfect osteogenesis results. Wasting, diarrhoea, mucosal hæmorrhages, periosteal proliferation and osteoporosis are manifestations of the condition.

While it may occur among sailors, hunters, and explorers who exist largely upon canned or dried foods, pathological fractures occur most often in infants and the young. The skull ribs, costochondral junctions and long bones are mainly affected by the disease. Fractures occur, as a rule in the thigh, leg and upper extremity. The diagnosis is made physically and by the X-ray. In the latter subperiosteal hæmorrhages with proliferation or periosteal elevation is generally observed. As treatment is continued the porosity of bone decreases and new layers of periosteum are noted.

The prognosis is very good. Treatment other than proper splinting consists of supplying vitamin C which is found in oranges, lemons, apples and bananas. As the majority of fractures occur in infants or the very young, practically speaking, the treatment consists of the administration of orange juice in adequate quantities.

Metabolic disturbances—Diabetes Pathological fractures occur among diabetic patients very rarely. It is questionable whether the fracture is a result of the metabolic disease or to associated disuse and atrophy.

Metabolic disturbances—hyperparathyroidism. Hyperplasia and also adenomatous changes of the parathyroid glands cause generalized osteoporosis. Pathological fractures may result.

Compere has recently analyzed 12 cases of hyperparathyroidism including one of his own. Five (42 per cent) of these developed fractures. Three (33 1/3 per cent) had had multiple fractures when reported. A recent personal case has had multiple fractures (Fig 19). On three occasions a parathyroid adenoma was removed and the result was pronounced improvement each time as regards health and hypercalcaemia. It is interesting to note that this patient has had many dozens of fractures and has lost exactly 3 feet in stature. Fifty eight per cent of Compere's collected cases were females. The average age was 37 years, the youngest being 7 and 14 years old and the oldest 59 years of age. The majority of them had been diagnosed as osteitis fibrosa. Eight of Compere's collected cases had an adenoma of the parathy-

roid gland. Another was not operated upon but had bilateral palpable tumors (Duken's Case 2). The cases of Boyd, Milgram and Stearns had cystic adenomata. Wilder's cases had undergone malignant degeneration. The personal case proved to have a cystic adenoma of a parathyroid. The blood calcium is increased and chemical studies of the urine and faeces show an excessive output of calcium. In addition to extreme generalized osteoporosis, hypotonicity of muscles and cystic degeneration of bones occur. Deformities are common.

The prognosis in the past has been hopeless but recent operative interference has results in marked improvement. Without operation (parathyroidectomy) the fractures unite slowly and tend to recur.

In addition to immobilization and extirpation of the diseased parathyroid glands, the treatment should be directed toward better calcium deposition. Before operation and after operation the absorption of calcium and phosphorus may be materially benefited by the administration of irradiated ergosterol or codliver oil, heliotherapy, and diet. Future study and literature regarding this interesting subject will eventually clarify the situation.

Fragility due to hereditary disease Osteogenesis imperfecta (Fig 20) Osteogenesis imperfecta is claimed to be an inherited diathesis of bone fragility as many as 9 individuals being affected in four generations. Multiple fractures occur more often in early life, almost exclusively before the thirtieth year.

Its etiology is little known and its terms are many. The various names confusing this condition are idiopathic osteopsathyrosis, fragilitas ossium, idiopathic fragilitas ossium, brittle bones with blue sclera, brittle bones, congenital rickets, juvenile osteomalacia, osteogenesis imperfecta congenita, osteogenesis imperfecta tarda, osteogenesis imperfecta, hereditary mesenchymic hypoplasia.

Patients suffering with this disease frequently have fractures from trivial traumata or muscular action. Cases are on record where fractures have occurred *in utero* and during passage through the birth canal. The latter should be remembered because of the medicolegal aspects. Usually though multiple fractures take place after birth. The X-ray reveals (except in the postadolescent age) extreme bone porosity and frequently many photographs have to be taken to secure a fair roentgenogram of the pathology. These patients frequently have blue sclera. The long bones of the extremities and the ribs are mainly affected.

In the pre-adolescent stage the fracture lines have a peculiar appearance and they seem to result from a crumpling or bending action, with frequently an attempt to telescope on one surface. This peculiarity is probably due to the fact that the bone is so decalcified as to be actually softened. The bowstring action of the powerful flexor and extensor muscles or torsion is then sufficient to crumple the softened bones. Despite the low calcium content of the bone, fractures heal quickly and with abundant callus. The blood calcium and phosphorus are usually normal or above normal as in hyperparathyroidism.

The immediate prognosis is good but recurrent fractures and premature death often result.

We have had occasion to observe or treat some 8 cases of this condition. In one instance multiple fractures occurred in twins 13 months old. In one family under observation the condition has been present for four generations—a later report will follow.

Osteosclerosis generalisata. Osteosclerosis generalisata has been described by several writers. In this condition all the bones seem to be abnormally hard or sclerotic. It is spoken of as marble bones. The bones are overcalcified (in comparison to osteogenesis imperfecta) and are entirely lacking in elasticity. The fracture line is often very straight (transverse) or steplike and resembles the breaking of limestone or marble. This condition occurs most often in the young. The etiology is not known but it has been considered to be the result of a hypervitaminosis. The X-ray picture is pathognomonic, as the bones are revealed to be extremely opaque.

The immediate prognosis is good. No difficulties are encountered as a rule regarding union, though it may be slightly delayed. The ultimate prognosis is guarded because recurrences are the rule. The tendency to fracture usually disappears after the age of 30 years (Babcock). Merrill has recently reported a case.

Gaucher's splenomegaly. In splenomegaly due to Gaucher's disease (at least) rarefaction of bone takes place. Practically all cases which have recently been subjected to X-ray examinations have shown bone changes. The osteoporosis may be so great as to result in pathological fracture. The lower ends of the femur seem to be oftentimes involved.

Welt *et al* have recently reported 6 cases of this disease, 50 per cent of which developed pathological fractures. The patients complain of pains in the bones, stiffness, and limp. The long bones of the lower and upper extremity are chiefly affected. In addition to the splenomegaly the

*Osteoid reaction that union has been known to occur in hypervitaminosis.

symptoms may resemble osteomyelitis and be operated upon for the same as was the experience of Moschowitz. The diagnosis is made by the blood findings, biopsy puncture and X-ray examination (Fig. 11).

The prognosis is not good. Splenectomy has added a number of cases in relieving the anemia, hemorrhagic diathesis, and burdensome weight of the organ, but it remains to be determined how curative the procedure is.

Fragility due to chemical irritation in industry. The absorption of certain chemicals in the body may lead to bony deposits of the metal and thence to necrosis. So called "fragilitas osium" among match dipper has been reported by Dearden. According to him, the bones of such workers contain an excess of phosphoric acid which combines with the pre-existing neutral phosphate to form a slightly acid salt and thereby cause excessive brittleness of the bones, i.e., phossy jaw.

Pearl workers' disease is (Da Costa) due to an osteitis from chemical irritation. Tillmans claims that arsenic and pyrogallol acid produce a similar ossifying periostitis. Pathological fracture due to the destruction of bone by mesothorium has been recorded by Martland. The fracture sustained was of the upper femur in a girl who painted watch dials with luminescent paint.

The treatment consists of eliminating the causative chemical when possible. The prognosis is

generally good as to union, but poor as to complication

ANALYSIS OF UNION IN PATHOLOGICAL FRACTURES

Non union of various grades to excessive union may occur in different types of pathological fracture or in the same disease

The vast majority of pathological fractures unite. Table IV shows that union may occur in 89 per cent of the different diseases and 20 per cent may have excessive callus production

Delayed union (but union nevertheless) may take place in 70 per cent. In only 16 per cent is non union the rule, though Bloodgood is aware of its occurrence in sarcoma hypernephroma and endothelioma. Ten per cent of this latter group are placed in the little known class as insufficient data on reported cases make this necessary. The pseudo fractures described by Milkman¹ probably should be included in the above.

SUMMARY

In fractures through benign tumors union is the rule. In cysts the fracture episode usually results in a cure of the cystic condition

In malignant tumors union often occurs. Hawley states that in carcinoma union is the rule. Bloodgood states that in metastatic carcinoma union rarely takes place. In Pancoast's experience 40 per cent of pathological fractures due to carcinoma unite—with or without irradiation

In sarcoma Bloodgood states that union is almost unheard of. 2 doubtful cases in his report of 22 examples. There has been union in a single case of endothelioma. Pancoast also Pfahler, report no union in their experiences. The patients usually die in bed of their metastases the fracture being incidental. Union is known to have occurred in malignant myeloma cases

Primary bone tumors have an incidence of fracture in 22.7 per cent of cases (Coley and Sharp)

In acute and subacute inflammatory condition union is the general end result, if the infection has early and adequate surgical treatment. In neglected cases especially in adults non union may occur

In chronic inflammatory conditions union is the rule with excessive callus formation

In fractures occurring in general disease, union is delayed or absent depending upon the course of the general disease. In rickets, osteomalacia and scurvy, proper treatment results in union—osteomalacia frequently heals with excessive provisional callus

Eighty nine per cent of causative conditions are known to have union occur, in most of which union is the rule

I take this opportunity to thank Dr H. K. Pancoast and his Department at the University of Pennsylvania Hospital and also Dr Burville Holmes and his Department at the Philadelphia General Hospital for the data furnished by them in the preparation of this article. I wish also to thank Dr Eugene Pendergrass who has so kindly written the X ray descriptions in the legends.

FRACTURES OF THE PELVIS

A SUMMARY OF TREATMENT AND RESULTS ATTAINED IN ONE HUNDRED AND EIGHTY FIVE CASES

LLOYD NOLAN, M.D., F.A.C.S., FAIRFIELD, ALABAMA

Chief Surgeon, Tennessee Coal, Iron and Railroad Company

H. EARLE CONWELL, M.D., F.A.C.S., FAIRFIELD, ALABAMA

Orthopedist, Employees Hospital

THREE years ago we reported before the Surgical Section of the American Medical Association a series of 125 fractures of the pelvis, these cases having been treated by us during the period from January 1, 1920 to July 1, 1928.

We now present for your consideration this series together with an additional 60 cases encountered and treated between July 1, 1928 and July 1, 1931, this constituting a total of 185 consecutive cases treated in an 11 year period.

TABLE I—ANATOMICAL DISTRIBUTION

	Left	Right
Ala of ilium	35	13
Superior ramus of pubis	30	24
Inferior ramus of pubis	05	27
Superior ramus of ischium	4	2
Inferior ramus of ischium	31	
Acetabulum	19	18
Separation of symphysis		12
Densate sacro iliac separation		1
Bilateral pelvic fractures		5
Fracture of sacrum with associated fractures of pelvis		10
Fracture of lumbar vertebra with associated fractures of pelvis		12
Isolated fractures of the tuberosity of ischium		1
Double vertical fracture of pelvis (Malgaigne)		6

It will be seen from Table I that very few of the fractures in this series of cases were single.

The ages of patients ranged from 2 to 87 years, with a general average of 36 years. The average stay in the hospital was 53 days. There were 141 male patients and 44 females. In 99 cases the fractures were the result of industrial accidents and 86 of civilian accidents. Of the latter 75 per cent were the result of automobile and motorcycle accidents. It is interesting to note that fractures of the pelvis in women during the first three years covered by this series, that is, from 1920 to 1923, constituted only 10 per cent of the total civilian accidents and that since 1923 fractures of the pelvis in women amount to almost 50 per cent of the total civilian cases. Over 70 per cent of these fractures of the pelvis in women were received in automobile accidents, and as far as we are able to judge, such fractures were caused by trauma of definitely less severity than that producing such fractures in men.

It is impossible to divide the severity of the cases in this series with regard to time lost. However, in reviewing the civilian and industrial accidents we feel that, while the severity of injury in each type of case was about equal, the civilian cases as a class were worse than the industrial accidents. Seventy-five of the civilians returned to their former duty and the remainder are earning a livelihood at some painful occupation. The number of days lost from work averaged 142, the industrial accidents losing an average of 154 days, and the civilian accidents returning to work in an average of 130 days; this difference in lost time we attribute largely to the provisions of the Compensation Law.

Sixty-four of the industrial accidents were complicated with other fractures or severe injury of the soft structures. The uncomplicated cases and 24 of the complicated cases returned to full duty without any permanent disability, while the remaining cases had disability ranging from 15 per cent to total disability. In no case was the pelvic fracture the only cause of disability as there were severe associated injuries in every instance. However, most of the disabled patients are earning a livelihood today at some lighter occupation.

Complications in these cases, listed in their order of frequency, were as follows: blood in urine; extraperitoneal hematomata; extraperitoneal rupture of the bladder; rupture of the deep urethra; intraperitoneal rupture of the bladder; laceration of the perineum; contusion and rupture of the kidney; injury to the rectum; fracture of the femur; dislocation of the hip; fracture of the spine; miscellaneous fractures. In 5 of the total 185 cases blood was found in the urine of these 26 patients had sustained rupture of the bladder, 8 intraperitoneal and 18 extraperitoneal. Eleven patients had either severe laceration or complete division of the deep urethra. In several of the severe cases the apparent tendency to the formation of renal and vesical calculi was very marked during the convalescent period.

There was a total of 30 deaths (16.2 per cent) in the 185 cases. Nineteen of these patients died within 24 hours following admission, all of whom had severe associated injuries which were regarded

Suspension and traction applied in case of fracture of the pelvis.

as necessarily fatal, and the most of them were practically moribund on admission to hospital. The remaining 11 patients died as follows: 3 within 48 hours, 3 within 72 hours, 2 within 3 days, 1 within 4 days, 1 within 32 days, 1 within 4 months. The causes of these deaths varied as follows: shock, pneumonia, rupture of intestines, intra-abdominal hemorrhage, pulmonary embolism, intrapelvic and intra-abdominal hemorrhage, rupture of rectum, rupture of the bladder and urethra, multiple fractures of the pelvis and spine, and general septicemia.

Since the publication of the previous series we have had a number of inquiries from obstetricians as to the effect on normal delivery of various fractures of the pelvis. It so happens that in our series we have observed very few pregnancies subsequent to injury. In one case it was necessary to perform a cesarean section because of impairment of the pelvic outlet. Therapeutic abortion was performed on two patients, one of whom became pregnant 2½ months and one 3½ months after injury. One patient whom we regarded as having only fair results has borne two children since injury. The first delivery which occurred about 2 years after injury was of the breech type; the second delivery 1½ years later, was accomplished by version and extraction. The patient stood both deliveries in a most excellent way. We believe that if pregnancy occurs within 5 months following a severe fracture of the pelvis, therapeutic abortion is indicated. Pregnancies occurring at later dates should be handled as indicated

by the condition of the pelvic ring. In certain cases cesarean section will be indicated. In many others we feel that normal delivery can be accomplished.

Only about 55 per cent of the total series of patients had what we regard as good anatomical position when discharged, but we are sure from our observation, that excellent functional results are frequent in cases in which good anatomical position is by no means secured. Open reduction for correction of displacement of bony fragments was done in only 2 cases, and then only to relieve pressure of the displaced fragment on the rectum and bladder. It is our opinion that what appears to be a poor position of the fragments is by no means a constant cause for persistent pain and disability. We have frequently observed that in cases in which there was marked displacement of fragments there was less pain and less disability than in others in which excellent position was secured. This at times is difficult to explain.

We are still of the opinion that a standardized method of treatment by use of the overhead pelvic suspension frame with traction on the lower extremities presented in our previous paper, will yield excellent results in a higher proportion of cases than any other method.

On admission to hospital complete X-ray examination is made of every patient, and in cases of severe shock this is done by the use of a portable machine at the bedside. Careful and painstaking physical examination is then made to determine as quickly as possible the extent of soft part

injuries. If gross blood is reported in the urine an immediate attempt is made to determine the source whether from urethra bladder or kidney. This, of course calls for considerable judgment and is not always easy as great harm may be done by injudicious instrumentation.

If intraperitoneal rupture of the bladder or other intra-abdominal visceral lesion is suspected laparotomy is performed as soon as the condition of the patient will allow. If extraperitoneal rupture of the bladder is suspected great care is taken in operating to prevent entrance into the peritoneal cavity. If the lesion is in a position to allow of suture, immediate closure is done. If not, very careful drainage both by incision and by catheter is practiced. In cases showing gross lesion of the posterior urethra immediate perineal urethrotomy is performed and whenever possible the urethral lesion is sutured. Drainage should be practiced in every case of gross injury to the bladder with extravasation, but we are definitely of the opinion that hematomata without urinary extravasation should not be drained unless secondary infection should occur. It is unnecessary to say that the treatment of these vesical and urethral injuries should include careful observation for weeks or months after the original injury.

Following careful examination and treatment of complications, the patient is placed in bed and treatment of the fracture begun with an overhead pelvic suspension frame suspension being obtained by a canvas sling or hammock which extends from the upper third of the thighs to the lower dorsal region. This hammock acts as an immobilizing factor because of the lateral compression action on the pelvic girdle the force being approximately equal to the body weight. This force is continually in action and, as relaxation of the muscles takes place, there is a constant tendency for the displaced fragments to fall into their natural position. Generally marked relief of pain is noticeable within the first few hours following the application of the pelvic hammock.

Suspension is supplemented in every case by traction on the legs and thighs, with about 15 to 20 degrees of abduction of the thighs at the hips. Abduction relieves the marked spasm of the strong adductors of the thighs and pelvis, prevents scissoring of the thighs, tends to pull the fragments back into place and prevents the limited abduction that is so commonly observed following these injuries.

The amount of weight on the hammock suspension is regulated by the weight of the body area which the hammock supports. It is our aim to use sufficient weight almost to counterbalance the

weight of the patient, but not enough to raise the patient completely from the bed. Weights used for leg traction vary from 4 to 8 pounds, depending on the size of the patient and the type of the fracture. Cases in which there is involvement of the posterior ring or sacro-fluac dislocation require more weight. It may be necessary to apply more weight on one side than the other depending on the presence of overriding.

Leg traction is used in all types of fracture of the pelvis except in those showing an isolated fracture of the anterior-superior or anterior-inferior spines of the crest of the ilium. In these cases only the hammock suspension is used, supplemented by flexion of the knees obtained by the use of pillows. Flexion in these cases should be about a 20 to 30 degree angle at the hips.

A spreader is used in certain cases to prevent too great a lateral pressure. Lateral pressure of the hammock may at times cause an overlapping at the points of fracture unless it is offset by the intelligent use of the spreader. The degree of lateral pressure can easily be governed by the raising or lowering of the wood spreader. The spreader should be the exact width of the individual's pelvis, within the canvas sling. The use of the spreader should be routine treatment except in cases in which a separation of the symphysis is present. In such cases a high degree of lateral pressure is necessary and is obtained by the use of the hammock without the spreader.

The method of treatment described gives a high degree of ease and comfort to the patient greatly simplifies nursing care, prevents a certain amount of muscular atrophy, allows for improved circulation throughout the pelvis, and provides easy access for care and dressings when the soft parts have been injured. In the simple uncomplicated cases it is rarely necessary to administer an anesthetic in application of the overhead pelvic frame and traction.

We believe that these fractures should be treated by traction and suspension for an average period of at least 42 days. At the end of this time the hammock is removed and the patient is allowed to move about in bed for another week. A pelvic belt is applied immediately after the removal of the hammock. At the end of the seventh or eighth week the patient is allowed out of bed and begins weight bearing with the aid of crutches.

Gradual increase of weight bearing is determined by the amount of callus formation as shown by X-rays and by the comfort of the patient as weight bearing is increased. In certain cases callus formation has definitely been hastened as in-

creased weight bearing is allowed but this method is resorted to only in carefully selected cases.

As convalescence proceeds, daily hot tub baths and local heat are used. Patients are kept under close observation at the orthopedic out clinic until full return to duty is permitted. We feel that a most important point in the securing of results is the keeping of these patients under close observation for a long period.

Judgment should be used in forcing these men back to work. In our early experience we were inclined to return them to work as early as possible but we frequently found that after a few days at work they were inclined to develop muscular

spasm of the back and thighs which necessitated return to bed with consequent lowering of morale. We attempt at all times to assure the patient that he has excellent prospects of recovery and that the long period of treatment in bed is not because of the expectation of a permanent disability but to enable the fractures to be immobilized long enough for union to take place.

We consider that close co-operation between the general surgeon and the orthopedist is necessary in order to secure the best results in these cases, the general surgeon handling complications of the soft parts and the orthopedist that part of the work falling under his jurisdiction.

POSTERIOR MARGINAL FRACTURE OF THE TIBIA

FRANK D. DICKSON, M.D., KANSAS CITY, MISSOURI

FROM the year 1768 when Percival Pott gave to medical literature his classical description of that fracture of the ankle which still bears his name down to the present day fractures of this region have continued to be a surgical problem of ever increasing interest. It is this fact that has given me courage to contribute some observations on the management of one of these fractures, the so-called posterior marginal fracture of the lower articular surface of the tibia. If additional incentive were needed it is the conviction that notwithstanding the wealth of literature available on the treatment of fractures of the ankle, the results generally obtained fall far short of what they should be. This is particularly true of posterior marginal fractures. Testimony to this is borne by the number of poor late results seen when any considerable number of

fractures of the ankle are checked up after the lapse of several years. Of the 15 posterior marginal fractures in this series 5 or 33 1/3 per cent were old fractures with malposition and disability.

Posterior marginal fractures comprise about 19 per cent of all fractures of the ankle joint according to Ashhurst and 10 per cent according to Speed and other writers. In a series of 93 fractures involving the ankle joint seen in our clinic 15 or 16.1 per cent were posterior marginal fractures. The lesion (Fig. 1) is one in which we have a fracture of the internal malleolus with the fracture line extending across the posterior surface of the tibia in such a way as to split off a part or the whole of the posterior margin of the lower articular surface of the tibia and a fracture of the lower end of the fibula, usually fow down. The deformity which results is a lateral displacement of the foot and a posterior dislocation of the ankle. Such an injury is in reality a bimalleolar fracture complicated by the splitting off of the posterior part of the lower articular surface of the tibia. It should be mentioned that a posterior marginal fracture may occur without displacement of the ankle (Fig. 2).

The suspicion that a bimalleolar fracture is complicated by a posterior marginal fracture should be aroused by two signs which Cotton has emphasized: (1) prominence of the anterior margin of the tibia which, however, is less as a rule than in complete dislocation of the ankle, (2) the marked instability of the ankle and consequent tendency for deformity to recur after reduction. A properly made roentgenogram

Fig. 1. Posterior marginal fracture showing posterior and lateral displacement of the foot.

Fig. 3, left. Posterior marginal fracture without posterior displacement of the foot.
Fig. 3. The result obtained in case shown in Figure 1.

Fig. 4. Posterior marginal fracture. A, Original injury. B, Failure to retain position after reduction and the application of a cast.

should clear up any doubt as to the character of the injury and lead to properly planned treatment. Apparently however, in a surprising number of cases although the bimalleolar fracture is recognized and the deformity corrected, the posterior marginal fracture is overlooked or the importance of completely reducing the posterior displacement of the ankle and accurately restoring the contour of the lower articular surface of the tibia is not appreciated. If this is not done after the fracture heals limitation of ankle flexion and extension remains, a painful ankle results which very definitely interferes with function and a permanent disability is established. In this fracture as in all ankle fractures accurate reduction is essential to a satisfactory functional result clinical evidence all points toward the conclusion that given a good anatomical reduction the functional result is rarely unsatisfactory.

TREATMENT

We have separated the cases of posterior marginal fracture seen in our clinic into three groups.

1. Fractures seen immediately following or within a few hours of the injury.
2. Fractures seen after a lapse of several days up to several weeks without reduction.
3. Fractures seen after several months or years with malposition.

The fractures seen shortly after the reception of the injury will as a rule, present no particular difficulty in reduction if a correct diagnosis has been made (Fig. 3). Under the general or local anesthesia, the knee should be flexed, to relax the tendo achillis, and the posterior part of the foot strongly adducted and inverted with the ankle in moderate equinus. Since the astragalus and the marginal fragment are attached to the fibula and in fracture of the ankle displaced with

Fig. 5. Posterior marginal fracture reduced by operation and beef bone screw used to hold fragments in place 4 months after reduction.

It seems logical that the primary step in reduction should be the correction of the fibular displacement. When sufficient adduction and inversion have been secured to correct the lateral displacement the foot should be pulled forward and brought into complete dorsal flexion. Dorsal flexion should make the posterior ligament, which is seldom torn, tense and so tend to mold the displaced fragment back into place and hold it there. A plaster cast is immediately applied and for two weeks is allowed to extend above the knee which is held in moderate flexion. Any tension on the tendo achillis should we believe be avoided for this length of time as it may cause a recurrence of the posterior dislocation and displacement of the marginal fragment. After 10

Fig. 6

Fig. 7A

Fig. 6. Posterior marginal fracture with recurrent posterior displacement after reduction showing Kirschner wire through the astragalus.

Fig. 8. Old posterior marginal fracture showing characteristic deformity in unreduced case. There is marked impingement of the posterior surface of the tibia against the superior surface of the astragalus.

days to 2 weeks the cast is cut down below the knee and the usual after treatment of fractures of the ankle followed. Weight bearing is not permitted under 8 weeks. The instability of the ankle in posterior marginal fractures should be constantly borne in mind and a checkup roentgenogram made immediately after the application of the cast. We are accustomed to check the position at least once or twice more during the first 10 days or 2 weeks following reduction.

From time to time we have had referred to us cases in which the posterior displacement has not been recognized or in which attempts to secure satisfactory reduction have been unsuccessful and the displacement has existed from several days to several weeks (Fig. 4). In such cases the problem of reduction is somewhat different from that in acute fractures. It is often difficult or

Fig. 7B

Fig. 7. A. Correction of posterior displacement shown in Figure 6 by skeletal traction. B. Final result in this patient.

impossible to influence the position of the displaced tibial fragment and maintain the anterior position of the foot. The difficulty in reducing the fragment is probably due to organizing procallus filling up of the space between the tibia and the fragment and to adhesions which have formed between the displaced fragment or fragments and the surrounding soft parts. In these older cases, if satisfactory reduction cannot be secured by manipulation, reduction by operation must be resorted to or some form of non-operative management employed which will successfully overcome the displacement. We have operated upon several cases in our clinic in some we have simply reduced the posterior displacement and put the marginal fragment in relation with the tibia. In others in which the fragment was large and the ankle seemed unstable following reduction, we have held the fragment in place with a beef bone screw (Fig 5). The results have been satisfactory if not perfect in all cases operated upon.

We have also used a non-operative type of treatment in these resistant cases which, although not sufficiently tested to allow positive conclusions to be drawn yet seems worthwhile describing. In this non-operative procedure the leg is encased in a plaster cast from above the knee to the ends of the toes, the cast being heavily padded about the lower end of the tibia. The front of the cast is then removed from the ends of the toes to the level of the lower end of the tibia only a posterior shell being left. A Kirschner wire is then passed through the astragalus and, using an overhead pulley direct traction is made upward or in reality forward, on the foot (Fig 6). Counter traction is supplied by the presence of the cast against the lower end of the tibia. Such traction is allowed to remain 3 weeks. In 3 cases in which this method has been used it was found quite efficient (Fig 7). It would seem that this method might be applicable in fresh fractures in which there is a tendency toward displacement after reduction as shown in the roentgenogram. In describing this method of direct skeletal traction, no claim of originality is made as it has probably been used by others in reducing this displacement but has not come to our attention.

In the old fractures with malunion we have, even if posterior displacement has been largely corrected, a filling in of the space between the tibia and the displaced fragment with callus which produces a deepening of the lower articular surface of the tibia from before back (Fig 8). The combination of even slight posterior dis-

placement of the astragalus and deepening of the lower tibial articular surface results in impingement of the lower end of the tibia against the posterior superior surface of the astragalus, limitation of flexion and extension of the ankle, and a painful point. In dealing with this situation a reconstruction type of operation is necessary and the results in our experience, while satisfactory so far as improvement of function is concerned, still leave much to be desired. Two types of operation have been used in our clinic. In one case, through two lateral incisions an osteotomy of the fibula was performed and the resisting structures around the internal and external malleoli were loosened until the astragalus could be displaced forward. The projecting posterior margin of the tibia was then resected until it ceased to impinge on the superior surface of the astragalus. The result was improved function to a satisfactory extent but still with much disability. In 2 cases the resisting structures were loosened up and the astragalus brought forward as in the preceding case but instead of resecting the posterior margin of the articular surface, a wedge of bone was removed corresponding to the excess callus, so far as we could estimate it, and the normal contour of the lower tibial articular surface restored approximately. The results in these 2 cases were better than in the first case, in our opinion, probably due to the fact that a more normal reconstruction of the lower articular surface of the tibia was secured. In a certain proportion of old cases with extreme deformity arthrodesis of the ankle should be the operation of choice.

CONCLUSIONS

From our experience with posterior marginal fractures, we draw the following conclusions:

1. Posterior marginal fractures of the ankle, if not properly reduced carry the certainty of resulting in marked disability.

2. Immediate reduction of both the lateral and posterior displacement should be carried out and the result checked by roentgenograms every few days for at least 10 days.

3. If adequate reduction cannot be secured by manipulation direct skeletal traction or reduction by operation must be resorted to.

4. Malposition in posterior marginal fractures may be improved by some form of reconstruction operation but impairment of function will remain.

5. If there is any question of the success of a reconstruction type of operation arthrodesis of the ankle should be performed.

COMPOUND FRACTURES OF THE LONG BONES

A REVIEW OF THREE HUNDRED AND FOUR CASES TREATED BY DÉBRIDEMENT CARREL DAKIN
TECHNIQUE OPEN REDUCTION AND PLATING WHEN INDICATED¹

GEORGE V. FOSTER M.D., F.A.C.S. PITTSBURGH, PENNSYLVANIA

From the Clinic of W. O'Neill Sherman, M.D., F.A.C.S.

DURING the past 15 years in this Clinic, certain definite surgical principles have been routinely adhered to in the treatment of compound fractures and this paper comprises a review of the results of 304 compound fractures of the long bones. These formed part of 7,069 fractures received by employees of the Carnegie Steel Company from 1917 to 1932 and of this number 2,440 34 per cent were compound fractures. This high percentage of compound fractures is indicative of the severe crushing type of trauma causing the injury. The 304 cases reviewed here comprise the compound long bone fractures which came under our care during this period.

These fractures were almost entirely sustained by direct violence and most of them showed extensive mutilation of the soft tissues. They were mainly in men employed in mines, steel mills or railways injured by falls of slate crushed by falling piles of steel or traumatized by coming in forcible contact with moving freight cars.

The majority of these fractures came into the hands of some member of this Clinic within 10 hours of the time the fracture was sustained, about 5 per cent were treated in other hospitals, following the principles outlined here and trans-

ferred under our care as soon as they had recovered from their shock.

The following principles are followed on all compound fractures regardless of their severity.

1 The wound associated with a compound fracture is looked upon as just as stirring an emergency as an acute abdominal condition and at least débridement is carried out with as short a lapse of time as possible. The limb is shaved the skin cleansed with soap ether and alcohol the crushed lifeless flesh is conservatively excised and the wound flushed out with Dakin's solution Vaseline gauze protects the wound margins.

2 Carrel tubes are put in place in the wound and over the wound immediately following the débridement, the limb is elevated and Dakin's solution is used to irrigate the wound sufficiently often to keep it saturated. Usually 2 drams of the solution in each tube are required every 2 hours. The dressing is changed every second day.

3 At the time of operation when the X ray plates are seen and also the wound itself with its associated bone injury a decision is reached as to the best and safest line of treatment to follow in an effort to obtain as good a reduction of the fracture as possible. Reduction may entail the curetting of the bone ends and approximation of the fragments with immediate application of a Sherman steel plate or screws the application of skeletal traction Kirschner wires adhesive traction with a proper splint or simply support with molded plaster coaptation splints. The treatment decided upon is carried out at the same time as the débridement is done.

4 The wound is left open. It may happen that to apply internal fixation the wound may have to be enlarged and then it is permissible to close the wound for a short distance but any attempt at complete closure is disastrous and unnecessary. In almost all cases the wound will have closed before the bone is sufficiently strong to bear weight and the unfortunate sequence of cellulitis, osteomyelitis, and possibly amputation should be sufficient to deter one from closing a compound fracture when nothing is gained by so doing.

5 The plate or screw if such is applied is removed as soon as union has taken place in the bone unless the wound has already healed over it.

Fig. 1. Case 3 J. P. Showing compound wound of femur on admission.

Fig. 2.

Fig. 3.

Fig. 4.

Fig. 5.

Fig. 2 Case 3, J. P. Anteroposterior view of compound fracture on admission.

Fig. 3 Case 3, J. P. Lateral view of fractured femur on admission showing fracture extending down to knee joint.

Fig. 4 Case 3, J. P. Showing anteroposterior view of femur 4 1/2 months after admission.

Fig. 5 Case 3, J. P. Showing lateral view of femur 4 1/2 months after admission.

We cannot stress too emphatically the necessity for an immediate adequate débridement and early institution of Carrel Dakin technique to these wounds. The débridement should consist of removal of all foreign bodies, blood clot tissues thickly impregnated with dirt and dead or dying muscle fascia, skin or periosteum the removal by sharp dissection of the wound edge until a healthy bleeding surface is obtained, the exploration cleansing and free drainage of all cavities. To excise satisfactorily the mutilated tissue in an extensive crushing wound requires a general anesthetic and considerable patience should be

exercised to make sure of leaving the wound absolutely clean. A delayed débridement or one done hurriedly, may lead to infection.

These compound fractures are divided into three classes depending upon the size of the resulting wound and the position of the bone fragments (16, 17). Appropriate well defined treatment is begun within a few minutes of the time of injury by a capable surgeon located at each individual plant. The area around the wound is shaved, cleansed with ether and alcohol, a Dakin dressing is applied and a well fitting splint put in place in an excellent manner and the man is then sent to one of the central hospitals with as short a lapse of time as possible. The man is kept in the hospital until almost complete function has returned so that he may be under our control and guidance and receive the advantages of our physiotherapy department. On discharge from the hospital in most cases he is able to return to light work immediately.

In describing the methods used in the treatment of these three divisions of compound fractures, 5 case reports are included at the end of each division. These were the 5 last cases of each group under our care at Western Pennsylvania Hospital before this data was compiled.

A. In extensive compound, comminuted fractures in which it is impossible to align the fragments satisfactorily and hold them with a steel plate, the wound is cleaned and thoroughly

Fig. 6. Case 3, J. P. Showing compound wound after skin grafting. Thiersch grafts used.

excised as described and skeletal traction, tongs, Kirschner wire or other forms of skin or skeletal traction is applied and the wound is irrigated thoroughly with Dakin's solution. In this class also we shall consider the fractures which though compound are in good position and require only the application of lateral coaptation splints after the débridement has been done.

CASE 1. J. B. 36 years old, injured March 28, 1930, at 4:45 P.M. when pile of steel beams fell on left lower leg almost completely severing the leg. He was treated for shock, a splint was applied and the man was sent to hospital. Examination revealed moderate shock, tremendous destruction of soft tissue and bone. The tibia and fibula were both badly comminuted. Eight hours after accident the wound was thoroughly cleaned under ethylene anesthesia and fragments of bone were put in place between the ends of the tibia. Lateral splints were applied and Carrel-Dakin treatment instituted. On April 17, 1930, it was seen that the comminuted fragments were so small that they would not unite to main fragments and they were removed. The original length of leg was preserved by insertion of Kirschner wires through os calcis and applying traction. On May 23, 1930, wires were removed from os calcis. On June 17, 1930, sequestrectomy of tibia was done. On August 25, 1930, entire healing of soft parts had taken place but there was a 1½ inch separation of fragments of tibia. There had been so much soft tissue destruction that it was felt that more healthy tissue would be necessary over the tibial crest to nourish the bone graft which would have to be put in place. Therefore between September 30, 1930, and October 28, 1930, a large pedicle skin flap was transferred from the right leg to replace the thin scar over the left tibial crest. The man was allowed up on crutches and sent home until time for bone graft. He returned in April, 1931, at which time a sliding bone graft was done with good union resulting. He has good knee motion and fair ankle motion at the present time.

CASE 2. W. G. 30 years old, negro injured May 7, 1930, at 10:15 P.M. Left leg was crushed between steel beams. Dakin dressing and Thomas splint were applied and he was transferred to the hospital. Examination disclosed a compound, comminuted fracture in upper third of left tibia and fibula, extensive laceration extending over knee joint on outer side of leg, laceration 1 inch in length over inner part of leg. At 1:20 A.M. under spinal anesthesia débridement was carried out. Carrel-Dakin technique was instituted and a Steilmann pin was inserted through the os calcis, and a 15 pound weight was attached, with leg in Thomas splint. June 18 wounds were almost healed so chlorazene ointment was applied instead of Dakin solution. Fibrous union was present lateral splints were applied and patient was encouraged to bear weight from July 1 to July 10, when he was discharged. Returned for physiotherapy until September 9, 1930, when he was sent to work.

CASE 3. J. P. (see X-ray prints and photographs) 45 years old Slav was injured May 15, 1930, at 4:15 A.M. when steel buggy ran over left thigh. The wound was cleaned, a sedative given, a splint was applied at mill and the man was sent to Western Pennsylvania Hospital. Examination revealed considerably shocked but conscious patient. Tissues of left thigh were crushed apart over the lower two-thirds of the thigh, the bone was badly comminuted and displaced. The femoral artery was exposed for 3 inches. At 9 A.M. after treatment for shock patient's thigh was thoroughly cleaned under spinal anesthesia, skeletal traction was applied to the lower end of the femur, a Thomas splint was put in place and 20 Carrel tubes were distributed about the wound. On May 26 temperature had risen to 104 degrees, 15 additional Carrel tubes were inserted and through and through irrigation was established. Temperature dropped to 100 degrees. Pressure pads were used to press the fragments into position. Good union was present and skeletal traction was removed June 17. Active traction was continued until July 10. The

large raw area was macroscopically clean on July 22 and 5 large Thiersch grafts were put in place. The skin was entirely healed by August 5. Treatment was begun with Morton Smart machine. Man was discharged on December 4, 1930, with instructions to return to work immediately. One inch shortening had been compensated by lift on shoe. There was 60 degrees motion in knee.

CASE 4. J. T. aged 37 years, steel worker. At 9:30 a.m. on January 21, 1931, a steel "buggy" ran over his right foot and leg. The skin was shaved, cleaned with ether, Dakin's compress was applied, a Cabot splint was put in place at the mill hospital, and the man was sent to Western Pennsylvania Hospital. Examination showed a compound fracture of the right fibula with laceration 2 inches in length just above the ankle joint. There was a simple fracture of the first and second cuneiform bones. All fractures were in good position. At 12 noon on January 21 debridement of the leg was done under novocain 1 per cent, plaster compression splints were applied, and the leg was elevated in Cabot splint. On February 13, the wound was completely healed and physiotherapy was begun with the Morton Smart machine. February 23 no further disability from fractured fibula was noted but there was considerable discomfort from the fracture of the cuneiform bones until his return to work June 7, 1931.

CASE 5. H. C. aged 36 years, bookkeeper injured September 1, 1931, 1:1 a.m. falling down 2 steps, receiving a compound, comminuted fracture of left tibia and fibula. He was brought to the hospital immediately. Examination showed a large piece of bone protruding from a wound $3\frac{1}{2}$ inches long on the outer lower third of tibia. X-ray films showed comminuted fracture at junction of lower and middle third of left tibia and fibula and simple fracture of internal and external malleoli. Patient was taken to operating room at 3:15 p.m., debridement of the wound under spinal anesthesia, but it was found im-

possible to reduce the fracture through this wound so an incision was made over the crest of the tibia. The wound was carefully blocked off and flaps and bones handled with non-touch technique. The bone fragments were cleaned with curette and Dakin's solution and jammed between the main fragments, thus preserving the original length of bone. A steel plate could not be applied owing to the comminution present. The operative wound was partially closed while the compound wound was left wide open. Carrel-Dakin technique was begun and the leg was cocooned in lateral plaster splints. On October 10 both wounds were entirely healed. On November 3 treatment with Smart machine was started though only fibrous union was present. Patient could not dorsiflex the foot. On December 1 patient was walking in double leg brace with aid of cane—good union and able to dorsiflex foot slightly. On December 22 he walked quite well with ability to dorsiflex foot 50 per cent and he had full knee motion. He returned to work January 2, 1932. Almost complete return of dorsiflexion of foot present by February and patient working steadily.

B. Primary plating (4) When the opening in the skin is at least 15 inches long and the fragments are not in position suitable for good union, a direct attack is made upon the bone immediately the ends curetted and put in good position, a Sherman vanadium steel plate applied, the wound left open and Carrel-Dakin treatment applied. In these cases the screws transfixing the plate to the bone are of such length that they go into the proximal cortex only and except in rare cases, do not go through the medullary canal and transfix

Fig. 16

 Fig. 18 Case 10 G G Lateral view of fracture after immediate reduction and application of plate

the other side. When it is necessary to engage a loose fragment on the opposite side of the medullary canal or when a transfixion screw alone is used to hold the fragments of a compound spiral fracture in place then it is quite permissible to send the screw through the canal. Lateral molded plaster splints are applied in such a way that the wound may be dressed without disturbing the supporting splints. The edges of the plaster splints about the open wound are protected with oiled silk to prevent the irrigating fluid from destroying the cast. It is rare that Dakin's solution softens a cast sufficiently in the course of treatment that it is necessary to build a second pair of splints. Dakinization is continued until the wound is only a small abrasion, then chlorazene ointment, zinc oxide or other mild protective is applied until the wound is entirely healed.

CASE 6. J. Z. (see roentgenograms) aged 24 years, was injured April 18, 1928, at 11:30 a.m., by falling 35 feet, alighting on a hard surface. Dressings were applied with Cabot splints at mill hospital and the man was sent to Western Pennsylvania Hospital. Examination showed a moderately shocked man with extensive compound fractures of both bones of both legs, simple fracture of both os calcis and dislocation of left ankle. On April 18, at 5:00 p.m., after treatment for shock, both legs were thoroughly cleaned of mutilated tissue under ethylene anesthesia and four screw Sherman plates were applied to each tibia. The wounds were left open and Carrel-Dakin treatment was instituted. The dislocation of the left ankle was reduced. On June 16, 1928, both plates were removed and the screw holes curetted. On August 20, 1928 firm union was present and patient was walking

with double leg irons. On March 21, 1930 both legs were entirely healed and patient was discharged to light work. Patient left work and returned on February 2, 1930, when a pedicle flap was put in place over the crest of the left tibia. It was later necessary to fuse both os calcis astragaloid joints. There is still some pain present in left os calcis-astragaloid joint.

CASE 7. M. B. aged 35 years. On March 11, 1930 at 7:30 a.m. patient's right forearm was caught between a crank arm and beam. The wound was cleaned, splint applied and he was sent to hospital immediately. Examination revealed a compound, comminuted fracture of the right radius with considerable displacement, a simple fracture of the right ulna with angulation. The wound was debrided at 11:35 a.m. under ethylene anesthesia, the ulnar angulation straightened and the fractures of the radius placed in good position and held by one screw. Anteroposterior plaster splints were applied and Carrel-Dakin treatment was instituted. On April 29, 1930, good union was in both bones. The wound healed and Morton-Smart treatment was begun. Patient was discharged to light work on May 13, 1930 with full motion present in wrist and elbow.

CASE 8. P. P. aged 60 years. May 17, 1930 was struck on the left leg by a flying piece of machinery as the result of an explosion. Two open wounds over the left tibia were cleaned, Cabot splint was applied at the mill hospital and man sent to city hospital. Examination showed compound fractures of the left tibia and fibula at junction of the upper and middle thirds and at the junction of the middle and lower thirds. Each compound wound was about the size of a 50 cent piece. The lower fracture of the tibia was comminuted. Man was in moderate shock. Under ether anesthesia, 4 hours after the accident, débridement of the wounds was done and a four screw Sherman plate was applied to the upper fragments and two transfixion screws held the lower fragments in excellent position. Lateral plaster splints were applied and Carrel-Dakin technique commenced, with leg elevated in a Cabot

Fig. 10, left. Case 14, B. C. Showing lateral view of compound fracture of tibia before secondary plating was done.

Fig. 10, Case 4, B. C. Secondary plating done 14 days after injury. Two attempts at closed reduction had failed. Plate healed in situ.

spinal. Men collapsed during the operation and artificial respiration and intravenous adrenalin were resorted to before he revived. On June 9, 1930, plaster splints were changed and the upper plate was removed. On July 5, 1930, screws in lower fracture were removed and screw holes drilled. Good union was present to both fractures. On July 8, 1930, the compound fracture wound was entirely healed and a Delbet splint was applied. Treatment with Morton Smart machine was commenced. On August 1, 1930, a walking Delbet splint was applied. On September 5, 1930, patient was discharged wearing only a single leg iron with firm union in fracture and 80 per cent motion in knee and ankle.

CASE 9. M. E. (see roentgenograms) Injured June 16, 1931 at 3:30 p. m., when he fell a distance of 15 feet, receiving a compound, comminuted fracture of the left tibia and fibula. The wound was cleaned with ether, a Dakin's compress was applied and a Thomas splint put in place at the mill hospital, and the man sent to Western Pennsylvania Hospital. Examination disclosed a 27 year old steel worker in slight shock. A fragment of the tibia was sticking through an open wound 4½ inches in length in the lower third of the left leg. At 5:00 p. m., June 16, a debridement was done under spinal anesthesia. The comminuted fragments were replaced after cleansing with a curette. A six screw Sherman vanadium steel plate was applied, the wound was left open, and the Carrel-Dakin technique was instituted. Lateral plaster splints were applied and the leg was elevated in a Cabot splint. After the second day temperature never rose to one hundred degrees. Carrel-Dakin treatment was continued until the leg was entirely healed on August 26, 1931. Physiotherapy in the form of Morton Smart treatment was begun and by September 15, 1931, firm union had taken place in the tibia. Man was given treatment for syphilis. Discharged to work on November 4, 1931 with the plate still in place.

CASE 10. G. G. On December 20, 1931, this 25 year old man fell 60 feet, injuring the whole of his right side. He was brought to the hospital immediately. Examination disclosed a compound fracture of the lower third of the right tibia and fibula with complete lateral dislocation of the ankle. The foot was blue and discolored. Patient was in shock. He was given a large intravenous injection of saline with adrenalin. Then 4 hours after the accident, a complete debridement and replacement of the fibula was done under spinal anesthesia. A 3 screw Sherman plate was applied to the tibia and Carrel-Dakin treatment was started with leg in plaster splints and elevated to a Cabot splint. Temperature never went above 100 degrees. Complete circulation returned in foot. On January 20, 1932, union was present, and plate was removed. On February 5, 1932, wound was almost entirely healed and patient was walking. He was to be discharged in 10 days.

C. Secondary plating (6) When the open wound is the size of a 50 cent piece or less and it has been decided that the fracture could be more accurately replaced by a direct attack and application of a plate than by extension, then debridement of the wound is carried out under local anesthetic, Carrel-Dakin technique is instituted, and an open reduction done later. Novocain, 1 per cent, is injected into the skin margins of the wound and proves to be sufficient anesthetic to allow a thorough debridement of such a small wound. The dangers of stirring up an infection by the injection of the novocain is negligible when it is done within the first 8 hours after the injury. This secondary plating may be done from 10 to 15 days after the injury, the time being decided by the temperature which must have been normal for 2 or 3 days, and by the condition of the open wound, which must have either healed or be microscopically clean. The limb must have returned to almost normal size the brush burns healed, and the edema and ecchymosis subsided. The plate is not applied through the open wound, but a fresh incision is made, away from the wound, the skin margins carefully blocked the plate applied with non-touch technique and the skin closed over it. In other words, it is treated as a simple fracture. In this series, 71 cases were secondarily plated and in 48 per cent, it was unnecessary to later remove the plate.

CASE 11. M. B., aged 25 years, was injured November 12, 1931, by being struck on left leg with a chisel. He was admitted to Youngstown Hospital where it was found that he had a compound, oblique fracture of tibia and fibula 4 inches above the left ankle. Debridement was carried out and position of bones improved by a closed reduction. Carrel-Dakin treatment was carried out on the two compound wounds. Owing to the fact that there was 3½ inch shortening in tibia, man was sent to Western Pennsylvania Hospital on December 7, 1931. Examination revealed two healthy compound wounds on lower part of left leg. Temperature was normal. On day after admission an open reduction was done and 4 screw Sherman plate was applied to tibia and operation wound was closed. Carrel-Dakin treatment was continued to the

compound wounds until healing took place January 2, 1929. Patient made an uneventful convalescence except for a general dermatitis of whole body due to a sensitivity to picric acid which had been used in preparing his leg. February 12, 1929, patient was walking with brace applied to leg; good union. March 19, 1929, he was discharged with 80 degrees knee motion and plate still in place.

CASE 12. G. G. aged 28 years, was injured January 30, 1929, by being crushed between battery machine and oven door. The right thigh was bleeding profusely from two puncture wounds. These were cleaned, packed with Dakin's gauze, Thomas splint applied, and the man was transferred to Western Pennsylvania Hospital. Examination showed the whole thigh crushed puncture wounds on anterior and posterior part of right thigh. The distal fragment of femur was displaced backward with $3\frac{1}{2}$ inches overriding. A Thomas splint with Buck's extension was applied after immediate débridement of both wounds, under novocain 1 per cent. Carrel-Dakin treatment was applied to the two compound wounds. On February 12, 1929, temperature had been normal for 5 days, and as closed reduction was not satisfactory under spinal anesthesia an open reduction of the femur was done away from the compound fracture wounds. A 6 screw Sherman plate was applied and the wound was closed. The leg was put up in Thomas splint in 45 degrees flexion. There was no postoperative temperature rise. On February 17, 1929, knee motion was commenced by patient elevating and lowering the Pierson attachment to Thomas splint through 45 degrees. Hairline reduction of fragments was shown by X-ray film. On April 17, 1929, firm union was noted and both wounds were closed. The Sherman plate had not been properly tempered and broke at the site of fracture. On May 1, 1929, patient was walking with caliper splint. On May 21, 1929, the broken plate was removed and the wound was closed lightly. On July 20, 1929, the patient was discharged to light work with 85 degrees motion in knee.

CASE 13. L. T., aged 55 years, was injured January 14, 1929, by slipping into a ditch. He received a wound on the left lower leg which was cleaned, a splint was applied at the mill and the man was sent to Western Pennsylvania Hospital. Examination disclosed a compound, comminuted fracture of the lower third of the left tibia with a wound the size of a 10 cent piece. The bones were not in contact. The leg was placed in Cabot splint after a débridement was done under novocain, 1 per cent, on admission. On January 25, 1929, when swelling had subsided and temperature had been normal for 3 days, an open reduction was done at a point away from the wound. A 4 screw Sherman vanadium steel plate was applied. The leg was put up in lateral compression splints, Carrel-Dakin treatment was carried out on the open wound, with the leg elevated in a Cabot splint. On March 12, 1929, he was receiving physiotherapy, and firm union present. Operative wound had healed by primary intention and original wound healed 2 weeks after operation. On March 31, 1929, he was walking in a leg brace. On March 26, 1929, he was discharged and on April 18, 1929, he returned to work.

CASE 14. B. C. aged 27 years. On April 30, 1931, at 7 a.m. patient was crushed by a steel "buggy" receiving multiple injuries to the left leg. His wounds were cleaned and a Thomas splint was applied at the mill emergency hospital. The man was then transferred to the Western Pennsylvania Hospital. Examination revealed a $2\frac{1}{2}$ inch laceration on the inner side of the left thigh the tissues were crushed and torn in the left popliteal space. The middle third of the left tibia showed a compound wound the size of a 25 cent piece on the lateral surface. The distal

Fig. 11. Photograph of compound comminuted fracture of tibia, showing an extensive wound partially closed. Sherman plate in place. lateral plaster splints applied in such a way that the wound could be dressed without removing the splint. Carrel tubes which entered every part of the wound are not shown.

fragment was displaced backward and there was no contact of surfaces. Kahn reaction 4+. At 12 noon on April 30, under spinal anesthesia débridement of the lacerations and wound was done and the laceration about the knee was closed. The fractured bone ends were replaced as accurately as possible and Carrel-Dakin treatment commenced on the open wound. On May 7, 1931, another attempt was made at closed reduction but check X-ray pictures showed that a sufficiently accurate reduction had not been obtained. On May 14, 1931, temperature was normal for 5 days and an open reduction was done with non touch technique about $1\frac{1}{2}$ inches away from the compound wound and the operative wound was closed tightly over the 4 screw plate. Carrel-Dakin treatment was continued to open wound and to crushed area in popliteal space. There was no rise in temperature after operation. On June 30, 1931, good union was found with plate in place. The wound healed. Thiersch grafts were put in place over the microscopically clean area in the popliteal space. On July 10, 1931, active motion with treatment by Morton Smart machine was begun. On August 27, 1931, the man was walking without a leg brace or cane and was discharged to work on October 2, 1931.

CASE 15. W. F., aged 43 years, was injured August 31, 1931, when a steel beam fell on his right leg at mill hospital wound was cleaned, gauze saturated with Dakin's was applied to the wound and a Cabot splint applied. Examination revealed a compound comminuted fracture of the lower half of the right tibia and fibula with fragments in poor position. The wound was thoroughly excised and cleaned under novocain 1 per cent and Carrel-Dakin technique was begun 3 hours after injury. On September 10, after temperature had been normal for 3 days and ecchymosis had subsided an open reduction was done at a part away from the compound fracture wound. A 4 screw Sherman steel plate was applied and the operative incision was closed. On November 5, 1931, firm union was present. Treatment was begun with the Morton Smart machine. The compound fracture wound healed. The man was greatly troubled with psoriasis. On November 20, 1931, the man was walking well, with a leg brace applied and 75 per cent motion was noted in the knee and ankle. December 29, 1931, for the past week there has been a slight serous discharge from the operative wound and since it was necessary to remove some hemorrhoids, it was decided also to remove the plate. This was done and the screw holes were curetted. Carrel-Dakin treatment was instituted, and the wound was completely closed, with free motion in knee and ankle on discharge from hospital on January 29, 1932.

Armamentarium (14) To obtain good results in reducing and plating fractures, one must treat the

soft tissues and bones with great respect other wise the contused tissues will more readily succumb to infection. Much can be accomplished by having the proper equipment with which readily and easily to reduce these fractures, with the minimum of trauma. To accomplish this one should have available Lane bone holding forceps, Lambotte bone and plate-holding forceps, Lowman bone clamps, bone skids, Smith-Petersen forceps, Berg forceps, Stille Sherman bone drill, and a wide variety of Sherman vanadium steel plates and screws. In certain instances, a Berg bone traction clamp is an essential instrument, as with it a fracture very difficult to reduce, is slipped into place easily and without trauma. A well prepared and stable (12, 13) Dakin's solution is the most important single item in the whole armamentarium of the treatment of compound fractures. The solution used in the treatment of these cases and referred to above as Dakin's solution is a 0.45 to 0.5 per cent sodium hypochlorite in hypertonic saline, this being a non-toxic, non-caustic, and non-irritating solution which has a high bactericidal power. In addition the solvent properties demonstrated by this fluid its ability to dissolve and wash away necrotic tissue, old blood etc. aids materially in cleaning the wound. A commercial product by the trade name of "Hycorite," the active ingredient of which is sodium hypochlorite 4.05 per cent, is the solution used in this clinic for the making of Dakin's solution. Seven parts of sterile water are mixed with one part of Hycorite to obtain the proper solution. This is made up daily and titration is unnecessary. If the solution is too caustic it is possible that it might absorb fresh callus, forming in fractures and Clay Murray (11) asserts that this has happened in some cases of compound fractures under his care, but certainly in this large series there has been no retardation of the formation of callus due to the irrigating fluid.

The dangers of non-union, osteomyelitis, cellulitis, and septicemia have been stressed by many writers when any observations are made regarding the advisability of openly reducing and plating compound fractures. In the early days of the war the British Army applied many steel plates in treating compound fractures, and it was later necessary to prohibit such practice. The reason for the untoward results leading to the abolition of the plates was that débridement was not carried out, nor was the Carrel-Dakin technique for the treatment of wounds known. Without the benefits of débridement or the knowledge

of the Carrel-Dakin technique, similar results would have been obtained in these cases, but it is the combination of these two procedures that eradicates the great danger in compound fractures—infection. Many writers both in the United States and abroad have based their judgment on the open reduction or plating of compound fractures on the results obtained during the early days of the war and not on the results obtained through the application of knowledge later developed. A Sherman vanadium steel plate or screw was applied in this series of cases when it was felt that such would give more accurate apposition of the fragments than could be secured in any other way. No hesitancy (10) was felt in applying a plate to the bone but rather a feeling of security knowing that the chance of the bone becoming displaced was reduced to a minimum and that the more accurate the contact of the fragments, the less the chance of non-union. There were no instances of septicemia, no cases of frank osteomyelitis, and no deaths due to infection in this series. Two patients only of the entire series died: 1 from pneumonia 5 weeks following an open reduction of a fractured tibia, the other from shock following a bone graft of the radius, 6 months after his original injury. In but 1 case an amputation was done on a tibia, plated 5 weeks previously. This was necessary due to the extensive trauma of the soft parts and blood vessels, with massive destruction of the bone, and not due to any infection. In many clinics the amputation would have been done immediately and, as it later proved, this was the procedure which should have been carried out. *The other three hundred and one cases returned to work in the mills, mines and railroads with good function.*

Incidence of chronic osteitis. In this series, if a discharging sinus was still present at the site of fractures or operation 4 months after injury it was assumed that chronic osteitis was present. This frequently consisted of only a small sequestrum and the sinus cleaned up rapidly after a sequestrectomy was done and the diseased bone was removed.

There were 22 cases of chronic osteitis in 150 cases of compound fractures which were subjected to débridement on admission, kept clean with Dakin's solution, and treated by traction or splinting. Seventeen patients developed chronic osteitis in 154 cases which had been openly reduced and in 129 of which a plate had been applied (Table I).

Briefly there was a discharging sinus present 4 months after injury in 11.6 per cent of the plated

TABLE I.—CHRONIC OSTEITIS IN COMPOUND FRACTURES

	Cases	Osteitis	Per cent
Openly reduced and plated			
Primary plating	58	9	15.5
Secondary plating	71	6	8.4
Combined per cent			11.6
Openly reduced			
Not plated	25	2	8.0
Not openly reduced			
Traction	52	10	19.2
Splinting	89	12	13.3
Combined per cent			15.7

cases and in 15.7 per cent of the cases treated by traction or splinting. These all eventually healed.

Incidence of non union. Non union was assumed to be present in this series, if the fractured bone was not firmly united 6 months following the injury (Table II).

In these 9 cases of non union only one case had any evidence of syphilis and as 14 per cent of these injured men do have a positive Wassermann it is felt that syphilis played no part in the failure of the bones to unite. All of these non unions were treated by bone grafts with subsequent union except the man who died of shock on the day of his operation.

To be absolutely fair, one must point out that the most severely comminuted fractures could not be plated and this fact probably raised the percentage of chronic osteitis and non union in the unplated fractures, owing to the fact that these two conditions more often develop in badly comminuted compound fractures.

Removal of plates. It has been our custom to remove the steel plates from compound fractures as soon as union has occurred. If however, the wound heals with the plate in place and it is not troubling the patient the plate is not removed. In this series of 58 primary platings, the plate was left *in situ* in 7 cases (12 per cent). In 71 cases of secondary platings, the plate was left in place in 34 patients (48 per cent). In simple fractures in our hospital the plate is rarely removed but remains untouched in at least 95 per cent of the cases.

In a review of these hospital records for this 15 year period (1917-1932) certain gradual changes were noticed in the method of treating compound fractures. One of the most noticeable was the fact that traction with moleskin adhesive has largely been supplanted by the surer traction of tongs or wires. This is especially true in compound fractures in which the irrigating fluid serves to loosen the adhesive too frequently. The length of complete immobility has also been greatly short-

TABLE II.—NON UNION IN COMPOUND FRACTURES

	Non-union Cases	Combined Per cent
Openly reduced and plated		
Primary plating	58	1
Secondary plating	71	1
Unplated fractures		
Opened	25	
Traction	52	3
Splinting	95	4

ened and active motion and graduated muscular exercise with the Morton Smart (15) machine, is begun even before there is X ray evidence of callus and when manipulation shows only a fibrous union to be present.

Diathermy has been dropped as a means of stimulating fracture union, whereas, 8 years ago it was felt to be essential to rapid repair.

In this series the open wound of the compound fracture was so extensive that 24 of the cases had full thickness skin grafts put in place to close the wound with the minimum of scar especially when the scar was over the tibial crest, where the blood supply is poor and ulceration is prone to develop. In extensively scarred wounds over ununited bones pedicle skin flaps were routinely put in place before grafting in order that the increased blood supply of the surrounding tissues would more certainly nourish the graft.

Any attempt at a review of the literature (1, 3, 5, 7, 9) written on this subject during the past 10 years would be foolish in the extreme as a wide variety of men working under divers conditions advocate many different methods of management. The trend in the past few years has undoubtedly been toward the more accurate apposition obtained by openly reducing these compound fractures when necessary. This, combined with the Carrel Dakin method of wound sterilization, not as a treatment after infection has set in but as a prophylaxis as soon as the injury is incurred gives the surest and safest method of handling compound fractures.

Dr W. O'Neill Sherman organized and supervised the method of treatment of almost all of these patients, and it is with his gracious permission that I am reporting these cases. To Dr Sherman and to Dr J. Huber Wagner, who also operated on many of these cases, I wish to express my sincere thanks.

SUMMARY

1. A series of 304 cases of compound fractures of the long bones of which 129 were openly reduced and plated.

2. The Carrel-Dakin technique was used in all cases to keep the wound clean and healthy and in addition accurately to appose the fragments an open reduction and plating was done when necessary.

3. The percentage of cases of non-union and chronic osteitis in the unplated fractures was greater than in the fractures which had been plated.

4. This series shows that the accurate open reduction and plating of a compound fracture in addition to the use of the Carrel-Dakin method of wound sterilization to the wide open wound tends toward rapid union without infection, rather than toward infection non-union septicæmia, amputation or death.

CONFERENCE ON TRAUMATIC SURGERY

INDUSTRIAL MEDICINE AND TRAUMATIC SURGERY

FRANKLIN H. MARTIN, M.D., F.A.C.S. CHICAGO

Director General, American College of Surgeons

THE Board on Industrial Medicine and Traumatic Surgery had its genesis during the Great War. Traditions and theories were ruthlessly cast aside. It was necessary to execute tasks expeditiously and efficiently, and with the greatest economy of management, money, and man power. It was advantageous to the government to develop every facility that would preserve health. Hence a committee on industrial medicine was organized by the Medical Section of the Council of National Defense.

In a word, this program demonstrated as never before that the employer and the employee could accomplish most if they worked harmoniously. The great leaders of industry, of labor, and of insurance composed their differences, to the great benefit of all concerned. This war experience was a progenitor of the Board under whose auspices this conference is being held.

In 1922, Dr. Daniel Z. Dunott convinced the Association of Railway Executives that railway employees would receive the most efficient care in hospitals approved by the American College of Surgeons. Forthwith by proclamation to the railroads, this association suggested that the em-

ployees of railroads so far as possible and practicable, should be treated in approved hospitals.

At the organization meeting of this Board held during the Montreal Clinical Congress in 1926, an important first principle was recognized. The leaders of industry, of labor, of the insurance and indemnity companies, and of compensation commissions must harmonize their interests. And it is an outstanding slogan of the College that if we can convince the heads of these groups we will be insured of the full, unqualified co-operation of assistants and associates. This principle is sympathetically endorsed by your chairman, Dr. Riesley.

The real work is already under way. We have held our conferences each year, and by correspondence we are in touch with everyone interested in the progressive work of this Board. During the past year two medical men have secured first hand information from the four groups with whom we must deal.

Up to this time we have been a fact-finding organization. It is our purpose to plan for the future. And we must all co-operate if we are to be of aid and if we are to solve the problems of industrial medicine and traumatic surgery.

SUMMARY OF A SURVEY OF MEDICAL AND SURGICAL SERVICE IN INDUSTRY IN NORTHWESTERN UNITED STATES

E. W. WILLIAMSON, M.D. CHICAGO

THIS report is based on a survey of 375 industries of various types in the central and eastern sections of the United States, the majority of which maintain a payroll of five hundred or more employees. Approximately three quarters of a million people are employed in these 375 industries, 178 companies (47 per cent) carry their own compensation insurance, 166 (44 per cent) are insured by indemnity companies, 31 (9 per cent) operate under the state fund or have

rejected the compensation act and are subject to the common law.

The following summary is based on the application of the Minimum Standard for Industrial Medicine and Traumatic Surgery as formulated by the College.

1. *Medical staff.* Industries have evolved various plans for the care of injuries incurred during employment of the 375 industries reported, 58 plants engage one or more full time physicians.

and maintain complete dispensary facilities 156 have part time physicians and operate a first aid room for the care of injuries and minor illness, while 161 have physicians only on call with limited or no facilities in the plant for medical care.

Plants which employ full time or at least half time physicians receive the benefits of active medical supervision and a more extended medical service, such as pre-employment and periodic physical examinations, diagnosis, and a service in preventive medicine. The physician is entrusted with the administration of the department.

Where the industry relies upon the services of a physician who is on call only there is little or no medical supervision. The reduction of employment this year has changed the status of many physicians from a part time to a call basis and under such conditions the nurse must assume more responsibility in providing relief and in deciding which cases should be sent to the physician for treatment. Injuries referred to a physician are usually treated in his office, so the plant operates for long periods of time without a visit by the physician. He is out of touch with the personnel and his only interest and responsibility lies in the care of the occasional patient who is referred to him. This type of organization of the medical service is too remote to be efficient.

2. Membership on the medical staff. The requirements for membership on the medical staff, as stated in paragraph 2 of the Minimum Standard for Industrial Medicine and Traumatic Surgery are fulfilled by the appointed physicians in almost all the industries visited. In two plants where no medical director is employed, the condition had arisen that non-medical practitioners were authorized to treat compensation cases outside the plant dispensary.

3. Clinical records. Many industries have a well organized and complete record system. It was found, however that in dispensaries of a large number of industries which employ an indemnity company to carry the compensation insurance the clinical records consist only of reports of cases treated in the dispensary. The employer is wholly dependent upon the carrier for the reports of cases treated in the surgeon's office or hospital. These records may be needed for reference in years to come perhaps after a change in insurance companies has been made therefore, records of all cases should be filed in the office or dispensary of the industry.

4. Hospitals. Where the operations of the industries are centralized one or more leading hospitals located conveniently to the plant are designated for the care of accident cases. This type of

industry uses only a small number of hospitals and the most of these are on the approved list of the College.

Companies which have a decentralized personnel, such as public utilities, usually specify that the injured employee be taken to the nearest hospital. The result of this arrangement is that a large number of institutions is used and the choice is made on the basis of proximity to the scene of accident rather than upon the rating of the hospital.

Aside from location, the selection of non-approved hospitals may be made by the employee who is not informed, by the physician who does not discriminate or by the one who pays the expenses because the rates may be lower. Industries should know more about the merits of an approved hospital and the reasons for the statement in the Minimum Standard that all patients requiring hospitalization shall be sent to approved institutions.

5. Medical supervision. Only the larger industries with physicians on a part time or full time basis have arranged for medical supervision of plant sanitation and health of employees. Plants which have the hazards of occupational disease are the most active in carrying out rigid measures in sanitary inspection and periodic examinations of employees who are exposed to these hazards.

There are problems arising in connection with the handling and settlement of occupational diseases which authorities state are much more difficult to solve than adjustment of compensable injuries. Many companies, especially the larger ones, which have operated under direction of the compensation law for 20 years, have carried on effective programs in the prevention of accidents and the care of injuries to the extent that loss of time and compensation therefore have been reduced extensively. Within some of these companies there are certain occupational diseases, such as silicosis, which are creating new and difficult situations. The affected trades are looking to the medical profession for assistance and a solution of these problems.

6. Scope of medical service. Only a small percentage of industries included in this survey extend medical treatment beyond the care of injuries and emergent and minor illness arising during working hours.

Of the 375 plants visited 330 maintained a dispensary with facilities sufficient to supply the specified service. The results of our studies show further that 241 (64.3 per cent) of the industries provide pre-employment physical examinations, while 115 (30.6 per cent) have periodic examina-

tions of all or certain groups of workers, 290 companies (77.3 per cent) have some form of benefit plan in operation, such as (1) a mutual aid association maintained by the employees alone or on a contributory basis. The benefits are weekly cash allowances for a stated period payable for loss of time due to illness and non-compensable

injuries. Only a small percentage of these associations provide the doctor's services. (2) A relief plan maintained by the company. (3) A group insurance plan which provides benefits for total disability and death, and in a small number of cases an allowance is provided also for illness and non-industrial injuries.

1932 SURVEYS OF MEDICAL SERVICE IN INDUSTRY

M. N. NEWQUIST M.D., CHICAGO

DURING the past year surveys have been made of the medical departments or services of varied industries at selected points in most of the United States. The purpose of these surveys, as directed by the Board on Industrial Medicine and Traumatic Surgery is to get the facts in regard to such medical service, to advance the efficiency of the service and to promote a better working co-operation between industry and the medical profession.

The surveys included 246 industries, representing a total of one million sixty two thousand employees or an average of four thousand employees each. Thirty-six per cent of the total employees involved had payroll deductions to provide complete medical and hospital service on some contract arrangement and in 6 per cent the families were included in this service. Seventy-five per cent of the industries visited had physicians either on a part time or full time basis and 70 per cent gave pre-employment physical examinations. Further organization for the provision of medical service appears to be inevitable. If the 36 per cent of employees mentioned wish to be served medically on some group insurance basis, would it not be possible and advisable to link up the doctor in some form of harmonious participation but still retain his identity and private status?

The plans and facilities for medical service ranged from no facilities or organized service whatsoever in the smaller industries to well equipped dispensaries and competent medical staffs in the larger or more hazardous industries. Most of the larger industries should be given credit and recognition for adequate care of their industrially ill and injured employees. To the smaller industries whose medical service is less efficient the efforts of the College in Industrial Medicine and Surgery should be directed.

Contract medical practice which originated in isolated industrial communities has received considerable impetus under the stress of the present prolonged economic depression. The following

conclusions in regard to contract practice are based upon observation and upon direct information from those who are involved in the practice.

Among the good points may be mentioned

- 1 The Group Insurance principle is utilized to provide medical care at low cost
- 2 It gives the employee and the employer a sense of security
- 3 Experience in this restricted field makes those that practice it more efficient.
4. Special facilities and full time service for the care of ill or injured are usually provided.
- 5 It fixes responsibility which is naturally considered an advantage by the employer
- 6 Uniform and prompt reports are rendered to the industry and to the State Compensation Department

7 It is a plan that can compete with the present day method of installment buying

Among the weak points and abuses are

- 1 Solicitation. In practically every instance there has been more or less solicitation either by the doctors or by paid lay solicitors.
- 2 Price cutting and bribery resulting in typical price wars.
- 3 It denies a reasonable latitude of choice of doctors or hospitals.
4. It permits the extremes of inferior medical and hospital services.
- 5 Unfair competition with the independent practitioner
- 6 Unreasonable demands made of the doctors.
- 7 Commercial exploitation of the profession. Commercial and other lay corporations are found practicing medicine
- 8 Medical and hospital service under contract practice is not always restricted to the low wage earner

It would seem that contract practice has its good points but inasmuch as it is subjected to so many abuses no blanket endorsement can be made of this type of practice. Each case must be judged upon its own merit.

INJURIES TO THE LUNG

AMBROSE L. LOCKWOOD M.D., C.M., F.A.C.S. F.R.C.S. (CAN) TORONTO, CANADA
Lockwood Clinic

IT was a great tragedy far beyond the imagination of any except medical officers with long service in advanced operating centers that not until the summer of 1916, after 2 years of intense fighting, were the possibilities of more radical intrathoracic surgical interference appreciated. In those 2 years thousands of lives were sacrificed that could have been saved if thoracic surgery had advanced as had surgery of other parts of the body. The success of that great master surgeon John B. Murphy and Sir William MacEwen in dealing with intrathoracic disease under ordinary general anaesthesia was entirely overlooked. The effort of Sauerbruch and his followers with the negative pressure chamber although it contributed somewhat to the advance in surgical technique of intrathoracic problems, served mainly to cloud the issue and render more absurd our knowledge of the physics of the chest and increased the tenacity of surgeons in dealing radically with intrathoracic conditions.

For 2 years of war we had watched hundreds of young men, the flower of the manhood of the nations die of chest wounds. Certain types of gunshot wounds of the chest were considered necessarily fatal and practically one hundred per cent of patients with such wounds died within 1 hour to 48 hours of being wounded. Approximately 78 per cent of all patients with thoracic wounds died. Largely as a result of the work of one surgeon in the French Army and two surgeons in the British Army—in the summer of 1916 and almost simultaneously although working separately the safety of radical intrathoracic surgery was determined and the mortality even in the so-called one hundred per cent "necessarily fatal" cases was reduced to 37 per cent. The vast number of such wounds dealt with during the last 3 years of the war firmly established the fact that the thorax could be widely opened, its contents be freely handled and dealt with, with less risk than in the routine abdominal procedures.

In addition, the convalescence was more rapid and complete and soldiers could be returned to their units for duty earlier than was the case in gunshot wounds of the abdomen, head, or extremities. This was no small consideration where man power was being so constantly and rapidly destroyed. Let us forget, may I point out that during the months of July August and Septem-

ber, 1916 sixty two thousand stretcher cases, entirely apart from walking-wounded, passed through our Casualty Clearing Station on the Somme front. Ninety beds were set aside for men with gunshot wounds of the thorax, whom the reception officers thought had a chance to recover. It was a distressing duty day after day as chief surgeon, to make hurried rounds of these patients and consign to the moribund ward those we knew would die within the next few hours. Appalled by our helplessness in dealing with wounds of this type and the distressing and inevitable outcome up to that period, and fortunately perhaps without any time or opportunity for confirming our conclusions by animal experimentation, we decided about the middle of July 1916 to attempt to deal radically with the so-called "necessarily fatal" type of gunshot wounds of the chest. Within 1 week, 11 so-called fatally wounded men, had been operated upon and were still alive. From that time on gunshot wounds of the chest in our Unit were considered as emergency surgical cases. They were immediately sent for admission to the resuscitation wards and we realized that chest cases requiring early operative treatment required it as urgently and as promptly as did abdominal cases. Operative interference became routine treatment. Our dread of such cases decreased as new experiences proved the value of radical treatment until by the autumn of 1916, we found that we had reversed our mortality and instead of helplessly watching 78 per cent of these unfortunate patients die we were saving 78 per cent of them (Lockwood and Nixon, (1)).

Thanks to the far-sighted policy of our Director General, the Adjutant Director of our particular army the IV British Army and the consultants, we were permitted to retain all chest cases after August, 1916 whether seriously or slightly wounded, until they were up and about, and able to do light duty. In addition, our own Casualty Clearing Station and that of Colonel Pierre Duval, now professor of surgery in Paris, were placed side by side. We worked in the closest of harmony and as he had been responsible for the development of thoracic surgery in the French Army we were naturally afforded an unrivalled opportunity to study our respective methods of dealing with such wounds. To Duval and his associates, my associates and myself will be forever grateful for

their great courteousness at all times, and for constant help and advice on matters surgical.

From 1915 to 1920 as a result of the tremendous casualties of the War and the dreadful epidemic of influenza in 1918 and 1919 with its high percentage of empyema thoracic surgery developed to a greater extent than it had in all previous time.

The successful treatment of empyema, lung abscess, bronchiectasis, tumors of the chest, surgical procedures on the heart and pericardium, the lungs, mediastinum and diaphragm and now successful operations for removal of the clot in pulmonary embolus, present an unparalleled galaxy of surgical achievement in the last 27 years.

It is a question if the profession generally, even yet, realize the great advances in the treatment of injuries of the lung made during that period, and the urgency and possibilities of treating such wounds in civil practice. A definite percentage of deaths after automobile and flying accidents, train wrecks falling from a height, crushing injuries, and penetrating wounds of the chest are avoidable if proper care is given.

At the outset the chief problem to be faced is the recognition of those patients who recover with out operation as distinguished from those who unless operated upon inevitably die. Speaking broadly the cases in which we advise a complete intrathoracic operation belong solely to the latter group.

It is not within the scope of this address to consider all types of traumatic lesions of the thorax. It must be appreciated however that most of the deaths due to thoracic injuries are due to extensive injuries to the bony skeleton of the thorax, the so-called stove in chests. Such patients die as a rule from the shock and exhaustion of the gross bony lesions. Injuries of the lung resulting from such accidents and conditions that should be recognized are:

1. Rupture of the visceral pleura causing (a) spontaneous pneumothorax in a closed chest (b) associated with an open pneumothorax—traumatopneuxia (c) the degree of displacement of heart and mediastinum in either condition.

2. The presence of a hemothorax—if so, how extensive?

3. A hematoma of the lung

4. Rupture of a main bronchus or blood vessel with escape of air or blood into the pleural cavity or mediastinum.

5. Contralateral collapse.

6. Massive collapse of one or even both lungs. Traumatopneuxia should be immediately sought for. If present, the wound should be cleaned and without an anesthetic the skin should be sutured

with deep silkworm gut sutures or be approximated and sealed over with adhesive plaster. The immediate improvement in such patients is often marvellous within a few minutes. The lung usually expands, the respirations become deeper, freer, and more regular, and the mental distress of such a wound is at once relieved. Such a patient can shortly be safely transported to a hospital for closer observation and further treatment.

Massive collapse of one lung and even of both lungs without any gross injury of the bony thorax occurs. This condition particularly that of bilateral collapse, we did not recognize until July, 1918, in the Ypres salient. The cause of it is difficult to explain unless due to sudden withdrawal of air due to bursting of a shell, with perhaps one intense expiratory effort and bronchial spasm. The lung or lungs were found contracted on their pedicle and were not larger than one third of the man's fist. While an excised portion would float there did not seem to be any air whatsoever in the entire lung. In such a case, the involved side is found to be absolutely silent. Place a handkerchief or a piece of gauze over the mouth, compress the nostrils of the patient, apply your own mouth to that of the patient, and blow air into his lung. The lungs can be inflated instantly, and with alternate blowing and pressure on the chest respirations can be restored. We no longer employ a pulmotor even for a patient suffering from asphyxiation.

Morphia in fractional doses should be freely administered and active resuscitatory measures taken to combat shock. Intense dyspnea due to hemothorax or pneumothorax should be relieved before operation by aspiration. If recurring hemorrhage is suspected the aspiration should be partial and combined with oxygen replacement.

Diagnosis. As soon as the patient's condition permits, he should be thoroughly examined by the surgeon, physician, and radiographer to decide whether or not immediate operation is required.

Röntgenological examination. Röntgenological examination reveals the approximate amount of hemothorax, the presence of pneumothorax, hematoma of the lung substance, the degree of collapse of the lungs, the position of the diaphragm, heart and mediastinum, and the compression and overriding of the ribs.

Clinical symptoms and signs. The physical examination should be limited in the first instance to ascertaining whether an immediate operation is advisable and possible.

Widespread surgical emphysema obliterates or disguises every other physical sign except the position of the heart.

Physical signs in traumatic lesions of the lung are most fallacious. Unduly moving the patient to permit of a meticulous physical examination is very unwise and the findings should not influence the decision to operate if certain indications for surgical interference exist. The bizarre findings on physical examination of traumatized chests must be realized by the examining doctors. Respiratory distress does not always accompany even the largest effusions. The degree of movement in a chest is not always proportionate to the intra-thoracic injury. Immobility may be complete without an intrathoracic lesion. Pneumothorax does not always develop rapidly after injury. It may be a late and gradual occurrence.

It has been a mystery to us why hemothorax so constantly develops in chest injuries. Seldom have we found an intercostal artery ruptured, or at least still bleeding rarely if ever have we seen active bleeding from a contused or lacerated lung except when it is held up by adhesions. Excision of a wound in the lung is associated with remarkably little hemorrhage.

Signs of increasing effusion in patients treated expectantly after 24 to 36 hours, are rarely ever due to active hemorrhage. Late secondary hemorrhage is, as a rule, due to bleeding from an intercostal artery.

Indications for operation 1 Operate on all patients with an open pneumothorax (trauma topnea).

2 Operate on all patients with laceration of the diaphragm as well.

3 Operate on all patients with a badly above in chest with overriding fragments and sharp spicules where the pleura is lacerated, even though there is no external wound.

4 Operate on all patients where a jagged irregular missile has traversed the pleural cavity whether lodged in (a) the chest wall, (b) the pleural cavity (c) the lung, (d) the mediastinum, or (e) the heart or pericardium.

5 Operate on all very acutely infected patients, even though the missile is not retained.

6 Operate on all patients with a penetrating wound of the chest with progressive bleeding, hemothysis, and massive hemothorax.

7 Operate on all patients with a massive pneumothorax and great displacement of the heart and mediastinum that cannot be controlled by aspiration.

8 Operate on all patients in whom rupture of a main bronchus or artery at the hilus of the lung is suspected.

Thoracotomy is rarely indicated for relief of the ordinary hemothorax or hematoma of the lung.

Unfortunately occasionally lung abscess or more rarely gangrene of the lung results from an extensive hematoma of the lung but unless thoracotomy is necessary otherwise, we believe such patients should be treated expectantly.

Anesthesia Surgeons dealing with thoracic problems should have a thorough knowledge of the physics of the chest. So many fallacies have been propounded based largely on experimental studies on dogs and rabbits. Such findings have little if any value as applied to humans. The mediastinum in the dog and the rabbit is permeable to air and even fluid but that of humans is impermeable and has a certain degree of fixation. Our decision to deal radically with intrathoracic wounds in 1916 was based on the fact that investigation on cadavers had established the fact that the mediastinum of humans was not permeable to air or fluids and presented a fairly rigid barrier between two cavities. Snyder's (3) investigations in 1927 corroborate our experiences of 1915 to 1919.

The modern gas oxygen machines with a snug fitting mask applied to the well vaselined face affords all the positive pressure necessary for re-oxygenation and offsets the danger of a prolonged open pneumothorax. Intratracheal gas oxygen anesthesia in the hands of an experienced anesthetist, should be employed for a prolonged thoracotomy.

A paravertebral anesthesia for two or three spaces above and below the wound or the site of the incision, with local infiltration, to avoid delay associated with gas oxygen anesthesia, is the anesthetic of choice. Emergency cases that would never be fit for a general anesthesia can be safely operated upon with this type of anesthesia. A more extensive, deliberate, and protracted operation can be undertaken with the minimum of shock to the patient. Respirations are deeper and more regular than with a general anesthesia, and the movements of the lung, mediastinum, and diaphragm can be voluntarily controlled by the patient to an appreciable extent. The two stage operation in which both sides of the thorax are opened, is possible only with this type of anesthesia. Postoperative restlessness, vomiting, retching, coughing and straining are avoided, and this plays no small part in the success of such operations, especially in bad risk patients.

Operation The complete intrathoracic operation must not be lightly undertaken. The preparations for operation, the anesthetic, and the technique of the operation are most exacting although the manipulations themselves within the thorax do not require any exceptional dexterity.

Speed is essential. *Absolute asepsis must be maintained.*

For operation the patient should be placed with the injured side dependent, usually in the half sitting posture. Primary union will not result without bold thorough excision of wound area.

When the position of the wound will permit resection of the fourth rib or preferably a long incision in the interspace immediately below from the mid-clavicular to the posterior axillary line furnishes easiest access to the thoracic cavity. A powerful snugly fitting rib retractor is necessary.

The commonest source of bleeding is from a torn intercostal artery. If the artery cannot readily be picked up and ligated with a small penosteal needle a suture can be passed around it or failing that around the rib itself.

The lung can be freely handled incised or a wound excised as required. If the wound is of a gaping type in the lung tags of intercostal fascia and muscle should be laid over the edges and sutures passed through them will relieve tension on friable lung tissue when the edges are approximated. Bronchial fistula will invariably be avoided if the visceral surfaces are carefully apposed.

Partial or even complete lobectomy may be necessary, depending on the degree of laceration of the lung. In such a case preserve plenty of the visceral pleura.

An open bronchus or alarming hemorrhage from the lung surface is rarely found at operation.

The toilet of the pleura must be meticulous.

The thoracotomy incision should be closed with a thick, moist towel every moment that the hands of the operator are not within the thorax.

Time should not be wasted in attempting to repair the parietal pleura.

The chest must be hermetically closed with the first layer of muscles otherwise pocketing will occur, pleural effusion accumulate, the incision break down, and an empyema result.

Careful approximation of the skin edges is necessary to insure early absolute primary union.

Drainage of the chest should never be employed in these primary operations.

Gross injuries of the bony wall of the chest associated with injury to the lung require that all comminuted bone and sharp spicules be widely excised. If the intercostal nerves have been torn, employ alcohol injection proximally to offset pain during convalescence.

Postoperative treatment. The postoperative treatment of chest wounds demands constant attention. The patient should be maintained in

the position found to be most comfortable. Oxygen should be employed if the patient is cyanosed. Morphia should be freely used to combat restlessness.

Aspiration should be carried out 18 hours after operation and as frequently as necessary to keep the pleural cavity relatively free of fluid. Early fluoroscopic examination or roentgenograms will help to determine the presence of a collection.

CONCLUSION

1. Grave traumatic lesions of the chest are still being overlooked, and are not being dealt with radically as they should be.

2. First aid instruction as to the necessity, urgency and methods of immediately sealing off a penetrating wound of the chest to overcome the ill effects of traumatopnea is advisable.

3. All such patients should be given morphia early.

4. Massive pneumothorax should be looked for. Active resuscitatory measures are necessary. In the majority of such cases blood transfusion is required.

5. The urgency of recognizing whether or not the thoracic lesion is the main cause of the patient's condition cannot be overemphasized.

6. The indications for thoracotomy are well defined.

7. The complete intrathoracic operation is a serious one and not lightly to be undertaken.

8. A select anesthesia must be employed.

9. Speed in operating and absolute asepsis are essential to success.

10. The operation must begin with *excision in toto* and end with hermetically sealing of thorax.

11. Fluid should not be allowed to collect in the pleural cavity after operation.

12. Resection and drainage secondarily should be a last resort. It is rarely necessary and should be employed only after multiple aspirations and if necessary catheter drainage has failed.

In no class of surgery is teamwork more essential to success. The surgeon, physician, radiographer, and anesthetist should work hand in hand. The theater staff must have everything prepared in advance and be quick and methodical, knowing each step in the operation, thereby avoiding delay. After operation nurses who are experienced in caring for such patients should, if possible, be employed.

SILICOSIS AND OTHER DUST DISEASES

C. O. SAPPINGTON, M.D., DR. P.H., CHICAGO

Director, Division of Industrial Health, National Safety Council

A DEPOSIT of silica in the lungs can never be removed. The health hazards to the operators on these dangerous jobs can all be eliminated, not only in such a way as to protect the operator but incidentally with a saving in production costs.

Silicosis, far from being a new disease was described by Ramazzini in 1700. The first American study was made by Lanza and Higgins, among the lead and zinc miners in the Joplin, Missouri district in 1914. Of the 720 miners examined 330 or 45.8 per cent, had silicosis in some stage 105, or 14.5 per cent, had silicosis with tuberculosis and 30 or 5.4 per cent, had tuberculosis alone.

Definition and etiology. Silicosis may be defined simply as a specific form of pneumoconiosis due to breathing air containing free silica dust—identified anatomically by generalized pulmonary fibrosis and the development of milary nodulations in both lungs clinically by shortness of breath decreased lung expansion, lessened capacity for work increased susceptibility to tuberculosis, and characteristic X ray findings.

It was formerly thought 10 years exposure was necessary for its production. Recent reports indicate that cases have occurred within 3 to 5 years exposure. The Canadian laws are based on an exposure of from 3 to 5 years.

The principal industries in which silicosis appears are (1) mining, (2) quarrying, (3) stone finishing, (4) pottery (5) abrasives, (6) glass, (7) mineral earth (8) spray coating, (9) refractories, and (10) construction.

Diagnosis. The diagnosis of silicosis rests on proof of adequate industrial exposure. Symptomatology physical and X ray findings the X ray findings being the most important.

In the *symptomatology* the outstanding preliminary complaints are non-productive cough and shortness of breath. These symptoms become more pronounced as the disease progresses. The X ray evidence is characteristic.

Pathology. According to Gardner in the initial stages the phagocytes are apparently irritated by ingested particles, transporting dust particles to points where intimate contact is established with connective tissue cells. Active proliferation of fibrous tissue continues after this stimulation and an extensive reticular network developed. Later

in the process a tendency to the development of discrete nodules is observed and hyaline degeneration of the nodules may take place. The normal flow of lymph from the lungs is interrupted by extensive damage and replacement by fibrous tissue in the tracheobronchial lymph nodes although the original degeneration of tissue is not due to an ischemic effect, but is essentially a local manifestation of the toxicity of free silica or quartz dust.

Prognosis. Prognosis depends upon the stage of development of the disease but is always grave from a curative standpoint when the changes are sufficiently advanced to be recognized clearly. The prevention of silicosis may be accomplished through observance of the following procedures:

1. A careful occupational history paying particular attention to previous exposure to free silica hazards the exclusion of those who have had exposure which might be hazardous, the exclusion of the tuberculous, and the refusal of employment to persons who are experienced in occupations involving a free silica hazard.

2. A careful physical examination and X-ray of the chest of all employees before going on work involving free silica hazards.

3. The provision of proper types of exhaust ventilation equipment, adapted especially to the processes involved.

4. Personal respiratory protection of an adequate and approved type, according to the manufacturing processes concerned, with proper provision for maintenance and supervision.

5. A periodic physical examination together with X ray examination of the chest at appropriate intervals, according to the severity of the exposure, the type of work done, and other detailed factors.

ASBESTOSIS

Asbestosis occurs with considerably less frequency than silicosis, although enough clinical and pathological material is now available for adequate study.

The disease may be defined as a specific form of pneumoconiosis due to breathing air containing asbestos dust, based on concentration and length of exposure. It is characterized anatomically by a generalized pulmonary fibrosis—clinically by shortness of breath and decreased

lung expansion and by X-ray findings which differ from those of silicosis.

Lynch and Smith surveyed all available literature on the subject in 1931 and collected 172 cases of pulmonary asbestosis. These observers stated that necropsy has been made in 18 cases, that including the first case recorded (that of Murray in the *Charing Cross Gazette* of 1900)

there are now four records of necropsy on uncomplicated pulmonary asbestosis. Most of these cases developed in the British Isles with the exception of a few reported by Simson in South Africa, by Lynch and Smith and by Pancoast and Pendergraft in the United States. Apparently the first American case recorded was reported by Soper in December 1930.

OCCUPATIONAL DISEASES

MEDICINE & UNCLAIMED PROVINCE

CAREY P. McCORD, M.D., CINCINNATI, OHIO
Medical Director, The Industrial Health Conservancy Laboratories

THE first factory in America probably was located in Jamestown, Virginia, in 1609. There Captain John Smith's little bands of pioneers made glass beads and similar bangles for trade with the Indians.

In this primitive foothold of American industry the threat of occupational diseases existed. Using the sands of the James River and lye leached from the wood ashes of their fireplaces, these first industrialists potentially were exposed to the causes of two occupational diseases that today stand out respectively as the commonest of such diseases and the most direful. Lye long has been a source of occupational skin disease—this country's most common significant trade affliction. Silica dust is the cause of silicosis—this country's foremost industrial disease problem. Occupational diseases thus have grown up with the country.

These two hazards, lurking in the first factory of 1609, have so multiplied until at this very time no fewer than 1,000 dissimilar dangers threaten the well-being of this country's workmen. These hazards are to be found in the vapors, gases, fumes, dusts, toxic liquids, noises, unusual chemical and physical rays, industrial bacteria, and many other creations of this country's far-flung industrial pursuits.

Today recognition is given to some 7,000 different occupations. Of these approximately four fifths are associated with some degree of prospective harm for the exposed workman. This number does not include as prospective traumatic injuries, which are distinct from occupational diseases, in that commonly they are swiftly produced, while long exposure is the rule in the case of occupational diseases. This may be clarified by

the simple example of a workman who uses an air drill in digging up a concrete roadway. A chip of concrete may lacerate the eye, thus immediately producing an obvious accidental injury. On the other hand, day by day vibrations of his pneumatic tool may slowly lead to a tenositis. This latter is not a fortuitous circumstance and the condition resulting from the sustained exposure constitutes a characteristic occupational disease. Although time is the essence of separation of industrial accidents from occupational diseases, no fixed time may be set as the demarcation line.

Some justification exists for maintaining that as many as 1,000 distinct occupational diseases may exist. However, while there may be 1,000 distinct causes of occupational diseases, the number of clinical entities is much less, owing to the fact that manifestations are essentially the same for many different industrial afflictions. Notably this is true of industrial dermatitis. Some idea of the frequency of cases of occupational diseases may be gained from the assertion that yearly 50,000 cases of occupational skin diseases alone take place. Other forms of occupational lesions are not proportionately large, but in the aggregate the yearly total throughout this country is enormous.

If, in fact, it is proper to recognize approximately 1,000 different occupational diseases, this number is believed to constitute the largest number of diseases falling into any one subdivision of medicine. However, with few exceptions, the number of cases of any one type of occupational disease in any one community is likely to be small. No less in every industrial area, week by week happenings like the following are likely to take place:

A. Recently in one city a department store worker presented herself to the physician in charge complaining of asthma. The faithful physician carried out numerous protein sensitization tests from feathers to pollens, without avail. The taking of a more careful work history would have disclosed that this department store worker was employed as a fur worker in the alteration room.

On cheap furs the brown and the black color may be procured through the use of *paraphenylenediamine*. This substance is a well known source of asthma, and this patient was suffering from a characteristic occupational disease.

B. In a low type of tobacco plant, two workmen are engaged in the reclaiming of scrap tobacco. This is a dusty process. Both of the men developed a disease characterized by peripheral neuritis, gastro intestinal involvement, upper respiratory tract inflammation, and loss of hair.

These two men were suffering from *arsenic poisoning*—due to the fact that in the growing of tobacco the plants are sprayed with an arsenic containing insecticide. This arsenic is retained on the leaves to some extent, and, given high concentrations of dust, arsenic poisoning is a reasonable expectancy.

C. In many cases the depression has caused persons to engage in dry cleaning on a petty scale. Fire regulations prevent the use of gasoline, kerosene, solvent, benzol, etc. Frequently these workers carry out dry cleaning in their homes—or in the rear of some other business building, using carbon tetrachloride as the flame proof detergent. *Chloroform poisoning* may be the result.

D. For long time *Malathion* insect powder which is made from chrysanthemum buds, was dusted about our homes in the elimination of insect pests.

Nowadays, it is customary to leech out the chrysanthemum buds with a solvent such as *ethylene dichloride* or *dichloroethane* and to spray the resulting fluid extract into the air. Both the solvent and the powder are toxic, and poisonings have arisen both in manufacturing plants and households. In the former the condition constitutes an occupational disease—in the latter a non-occupational affection.

E. During the hunting season for rabbits we find another example. Among the many butchers who dress rabbits for the market, several may prick or cut their skins—and *tetanus* may develop. Under these circumstances *tetanus* constitutes a clear-cut occupational disease.

F. Many workers, in cleaning up after a day's work, favor the use of abrasive soaps. The abrasive employed is likely to be *silica* or *silicic acid*. The makers of this type of soap are far removed from granite quarrying, sandstone cutting, or sandblasting, but no less *silicosis* may arise among them.

G. Saw mill hands are not infrequently engaged in handling logs that long have been floated about in mill ponds. These logs are likely to be covered with a rich growth of *fungi* (molds). Certain of these *fungi* are pathogenic and pulmonary diseases due to *fungi* are to be recognized as occupational.

Occurrences of occupational diseases such as the foregoing are frequently taking place all about us. These diseases reach into every specialty in medicine—not excluding surgery. In substantiation, I am citing the following:

A. In an eastern plant a number of workers proved to be suffering from bladder tumors. It was observed that all these workers came from one department. It was further observed that all were working with *benzidine*.

These cases, now under observation, are regarded as *benzidine tumors* but other derivatives of aniline oil are

known to be capable of producing similar neoplasms. These conditions are clearly within the domain of surgery.

B. *Silicosis* is followed, in a high percentage of incidence, by *tuberculosis*. In the treatment of ordinary tuberculosis, surgeons frequently resort to collapse of the lung. At once the question arises as to whether or not tuberculosis is a lung made dense by previous silicosis may be collapsed, and whether or not this is a desirable procedure. At the present time the answer to this question is not known, but some responsibility for the proper solution rests upon the surgeon.

C. *Silic sulphate* as formed about galvanizing plants, is quite capable of causing ulcers of the stomach and duodenum. To a lesser extent this is true of other metals and metal salts. The incidence of gastric ulcers among lead workers is considerably higher than for all workers.

D. Many thousands of workers in this country are exposed to *oils* and other *coal tar* or *petroleum derivatives* containing carcinogenic agents.

In England the frequency of *bar cancers* among textile workers makes of this a foremost problem. In this country either the incidence is lower or the recognition of cancers as occupational in origin is not accomplished.

These and many other occupational disease problems, clearly fall within the domain of the surgeon. Associated with the majority of all trades are clear cut dangers, leading to disabling and life-shortening abnormalities. Something may be gained by citation of one example chosen at random.

The uninitiated are unlikely to see any real dangers in the work of a metal polisher or buffer sitting or standing for 8 hours a day bringing various small metal objects into contact with a revolving cotton wheel or a similar wheel to the edge of which emery powder has been glued. To the initiated a number of distinct occupational disease hazards exist. These I am briefly enumerating.

1. Lead is nearly always present as an impurity in buffed or polished metals. Some metal parts so treated, are composed entirely of lead, or contain a high percentage of lead, 60 or 80 per cent, for example. Some lead articles are polished and buffed without plating, which means that any metallic dust generated is necessarily lead.

2. Some buffing wheels, or *adjuvants* used in buffing are *siliceous* particularly is this true in sand buffing. Although the sand may be treated with oils to prevent dust and to promote buffing, siliceous dusts are no less developed and *silicosis* is known to exist among these workers.

3. The revolving polishing or buffing wheel is never a circle due to inescapable unevenness. This leads to jerking and pulling on the hands holding the object against the wheel, which may eventuate and practically does eventuate, in *tendonitis* and kindred inflammations.

4. The polishing materials vary widely depending upon the metals being finished. Many of these

are skin irritants, of which chromium used in the buffing of chromium plated articles is the most dangerous. In other polishes silica or silicates are included.

5. On certain plated objects coming up to the polishers and buffers there is a scum or film. This is likely to be partly composed of the plating materials in spite of the fact that one or more washings may have followed submersion in the plating material. In chromium plating such a film is well known. Here is a small hazard for the production of skin diseases among polishers and buffers.

6. If the objects to be polished or buffed have bright surfaces as they usually do they may so reflect overhead lights as thus to produce a specular glare and create an eye hazard for the workman.

In addition to these characteristic hazards there are certain other important, but non-characteristic, ones. Tuberculosis rates are enormously high among polishers and buffers. The reason for this is perhaps several fold including the miscellaneous dusts provided and the posture assumed in polishing and buffing which limits breathing. This situation is well summed up by Hayhurst, who states. Especially should medical supervision be adopted for polishers and buffers as they are at a process which appears to take about 20 to 25 years off of their lives.

In the stream of constructive endeavor in industrial human relations occupational diseases have long been caught in an eddy. In the causation of this eddy the medical profession has played a prominent and unpraiseworthy part. The reason for this readily may be delineated. The ingenuity of the industrial chemist long has set too rapid a pace for the physician. By the time that the physician has familiarized himself with one set of hazards, the chemist has created substitutes which at times are equally dangerous. By the time the physician came to accept benzol as a highly treacherous solvent—the chemist was thinking in terms of glycols, higher alcohols, chlorinated hydrocarbons, xylenols, etc. The physician seeks refuge in what has now become a medical aphorism—*Occupational diseases do not lend themselves to ready diagnosis*. To the contrary, occupational diseases more than any other class of diseases of large numbers, lend themselves to precise and exact diagnosis!

The citation of excerpts from a single case may emphasize this situation.

A few years ago, a patient presented himself at the dispensary of a large hospital, giving his occupation as a windowshade maker and complaining of a widely distributed skin lesion. In the absence of a positive Wassermann, and

because of an earlier history of possible lues a diagnosis of that condition was made, and this patient was given arsenicals. The condition became worse and this afflicted patient sought no further treatment.

Shortly thereafter he appeared in another hospital as a house patient where, after consultation, a diagnosis of Hodgkin's disease was made for which there was some justification. The physician in charge was a friend to remove his patient to a home for incurables, since the prospects of recovery were negligible. However before actual removal this patient developed a thrombo-angitis in an extremity and a diagnosis of Buerger's disease was made. Later in the home for incurables, the physician recommended the removal of all teeth because of oral infection. The patient did not improve. However after many months, this man apparently did recover and worked for 3 years. During this time a full measure of the true facts had come to light. This patient was, in fact, a windowshade maker. However he worked as a pigment blender in the windowshade coating room—and analysis of these pigments disclosed a well known intoxicant as an impurity in the majority. This same toxic substance was found in the cut hair of the patient—in his urine—and in his blood. This patient's skin lesion—loss of nails—loss of hair—the angitis—the burning of his skin—all might have been attributed to the action of this intoxicant. *This workman was suffering from an occupational disease—arsenic poisoning!*

It is to be doubted that the defensive aphorism *Occupational diseases do not lend themselves to ready diagnosis* is a proper substitute for a generous lot of divine inquisitiveness.

As a result of the general situation contemplated occupational diseases represent a field of medicine much shunned by the great majority of physicians and surgeons. As a further result, much of the so-called authoritative medical testimony before courts is not only ludicrous but constitutes a prostitution of good medicine. Caution and good faith deter the good physician or surgeon from participating in court work when he is not on familiar footing. Consequently, testimony with respect to occupational diseases too often is of a low order—emanating from the mouths of so-called 'experts,' who, in fact, are illly qualified to present facts.

Recently during the life of a patient, who subsequently died, a consultant made a diagnosis of "chronic benzene poisoning." The family physician, being less versed in occupational diseases than in alkaloidal poisoning without evil intent, made his many court reports to read "chronic bromine poisoning." It is quite unlikely that the victim ever saw any bromine, yet the financial integrity of this dead man's dependents was jeopardized by this physician's act.

Not long ago I heard a reputable surgeon testify in a court, dealing with an occupational disease claim, that dusts entering the lungs exert a beneficent action. Dusts, it was affirmed, by their gentle irritation of the respiratory tract, serve to tone the tissues against infection. The *Journal of the American Medical Association* recently published a court decision in which lead poisoning (in Idaho) was adjudged to be an accident and not an occupational disease, because the period of exposure was only 3 weeks, and thus too short a time to produce an occupational dis-

case. Behind this travesty and I trust this remark constitutes no contempt of court, undoubtedly lies the testimony of some one or more physicians.

Failure to accept responsibility for occupational disease is hurtful to the status of the entire medical profession. Failure to delve into the precise activities of a worker who has become a patient frequently paves the way for much social injustice and medical inaccuracy.

In 1700 Ramazzini, the forerunner of occupational disease work, in his *Diseases of Artificers and Tradesmen* soundly observed in the preface that every physician should not only ask his patient— what uneasiness he is under how many days he has been ill how his belly stands, what food he eats but also “ what trade is he of? If that interrogation was important

two hundred years ago, how much more needful is it today! Moreover it is not sufficient to ask,

“ What trade is he of? ” for in our day most trades are highly subdivided. In Ramazzini's time it was sufficient to establish that a worker was a shoemaker but today the shoemaker's work is divided into three hundred operations, from archers to welt makers, each with its particular degree of danger for the exposed workman.

Whether or not the physician wills it, he is faced with the fact that occupational diseases are real numerous, severe, and costly. So clearly do they fall within the field of the practice of medicine that they may not be ignored. During the work decades of life second only to infection, occupation is the most potent cause of incapacity!

THE CARE OF EMPLOYEES IN INDUSTRY BY PHYSICIANS AND SURGEONS IN INDEPENDENT PRACTICE

FREDERICK W SLOBE, M D., CHICAGO

THE scope of this paper concerns the care of employees in industry by physicians who are not engaged in a full time capacity with one corporation. As the companies with which such physicians deal are usually small, a physician may have connections with a few or with a great many corporations depending upon their size and the percentage of the physician's practice which is in industrial in type.

About 99 per cent of the corporations in this country employ less than 1,000 men and in this 99 per cent are employed about 30,000,000 men and women. Of this vast number of employees, perhaps 80 per cent are employed by corporations which do not have full time physicians hence are given industrial care by doctors in independent practice. These figures furnish ample evidence of the importance of this subject. They should focus the attention of every physician who elects to treat the industrially disabled upon the obligation attached thereto likewise they should impress all medical organizations and physicians who though not interested individually in industrial care, should be responsive to the duties of the medical profession in this rapidly growing field of endeavor.

In the industrial centers where corporation practice is more standardized, private and industrial practice are not readily miscible, so physicians who having a liking for corporation practice or for traumatic surgery and whose industrial contacts show gradual enlargement, soon find themselves practically full time in their field of endeavor even though not full time with any one corporation. The special fields of traumatic surgery and of industrial medicine (whether considered separately or linked together) are of such scope as to merit the fullest recognition by the medical profession and the public. This recognition is vital if these specialties are to keep pace with the increasing demands made upon them.

In this industrial medical evolution some physicians, inclined toward the medical side of practice have emerged as specialists in industrial medicine and hygiene, others, surgically bent, prefer to be known as specialists in traumatic surgery. In both instances conducting a concurrent private practice is usually precluded. It is fitting therefore, that those qualified receive recognition as specialists in their field and that such recognition

be based on ability and not on the mere fact that a physician is confining his major activities to industrial practice. This process of selective recognition will attract young physicians of higher caliber to this field which will redound to the benefit of the employees in industry.

A physician dealing with many widely diversified industries has the opportunity of developing a breadth of outlook and a wealth of experience which is obtainable with much greater difficulty by a physician spending his entire time with one corporation unless that corporation is extremely large. At the same time he is subject to the disadvantage of not having sufficient intimacy of contact with any one company to enable him to fulfill many of the requirements of a complete industrial service.

Fundamentally, all employees are entitled to the same standard of medical supervision and service irrespective of the size of the company and regardless of whether a full time physician is in charge or a part time doctor in independent practice. Assuming this inherent right of the employees what are the essentials of factory medical service?

Briefly, the duties which a plant physician should be called upon to perform are the following: the care of those injuries, diseases, and abnormal conditions covered by the compensation law; the rehabilitation of the industrially disabled; conducting pre-employment medical examinations and periodical re-examinations during employment; the eradication of accident and health hazards; the prevention of the spread of communicable diseases in the plant; the regulation of factory hygiene and sanitation; co-operation with the employment manager in the selection of jobs to fit the physical and mental status of the individual; the supervision of physical defects and ailments not caused by employment in order to maintain efficiency and prevent loss of time; general health instruction to the factory personnel and finally the maintenance of a friendly contact with the employees' family physicians. In this latter connection it is understood that the domain of the family doctor is not invaded. On the contrary, the insistence of the plant physician will send many patients to their own doctors for the correction of physical defects or the care of bodily ailments, often unrecognized previously.

Now if we scrutinize the foregoing duties of the plant physician how many of them do we find performed in the average instance? Unfortunately in most cases we find the physician's contact with a factory practically limited to the care of accidents and diseases for which the employer is legally responsible. Are the physicians so negligent in their realization of the potential possibilities of an adequate industrial service or are there other fundamental factors at fault? Much has been said about the ineffectiveness of physicians in dealing with industrial problems—and there is no denying there is some justification for this criticism—but far too little has been said concerning the backwardness of corporations in recognizing the necessity for a complete medical service. It can be stated with confidence that practically every physician in independent practice would be only too glad to comply in so far as he is able with any request made by any company for some service in addition to the routine care of the injured. But such requests are so seldom forthcoming as definitely to dampen any enthusiasm with which the physician might be unbued to enlarge the scope of his affiliation with the factory. This apathy of the smaller corporations is exceedingly deterrent in frustrating the right of their employees to receive the same degree of general medical supervision obtained by those employed by larger corporations having full time physicians.

Our profession should aid in sponsoring an intensive educational campaign to apprise the heads of corporations with the dividends which an adequate medical service pays. Likewise, the matter should be brought before the labor organizations and before the public. If industry makes the demand, surely the medical profession will meet it, just as it almost invariably has met other demands in the past. Physicians doing a small amount of corporation practice who might not be ideally prepared to meet these new phases of industrial service either would have to equip themselves mentally to meet the new conditions or else risk losing whatever corporation contacts they might have acquired. Education of the profession, while essential, will be futile in solving the problem unless corporation consciousness is concurrently awakened.

The apathy displayed by most corporations toward their medical service is almost incomprehensible. The average factory superintendent engrossed in his study of production costs, pays little heed to the care of his sick and injured, seemingly oblivious to the vital, though somewhat intangible, rôle the welfare of his workers plays in his balance sheets. Before relegating the care of

his employees to a certain physician, the head of a factory should investigate that physician's qualifications with the same degree of care exercised in the selection of a physician for his own family.

Another factor in causing this disinterest of the employer arises directly out of the placing of compensation insurance. After receiving insurance coverage, the employer only too frequently selects any conveniently located doctor or accepts without question the physician designated by the insurance carrier. Having paid his insurance premium he is disinclined to expend further funds, feeling that he has met the requirements of the compensation law and that the burden now rests with the insurance company. The insurance carrier quite naturally is concerned only with fulfilling the requirements of the policy in force and thus all the employee receives is minimal service. It is obviously impractical for most corporations to be self insurers but if they were they would be far more analytical and critical in their selection of medical service than they are now.

A similar situation exists in connection with pre-employment examinations, the great value of which is appreciated by all physicians doing industrial practice but is absolutely unappreciated by the vast majority of the smaller corporations. Such examinations are not inimical to the work men, any criticism from their standpoint being more than offset by the early detection of unrecognized physical defects and ailments. Any overtures in this connection made by the plant physician are likely to be viewed askance by the company officials, both on account of the cost and because they are likely to feel the physician is merely trying to increase his own revenue. Were such examinations made legally compulsory both the employer and employee—and that means industry as a whole—would benefit.

Though perhaps apparently irrelevant to this subject the custom of carrying compensation insurance actually has a very decided effect on the relationship between the factory and the physician in independent practice. As such insurance coverage is and doubtless will continue to be an almost universal procedure a study of remedial measures would be timely. For example, if the workmen's compensation laws contained provisions covering the needed additions to the present limited medical service, the situation would be clarified greatly. This would necessitate either corresponding changes in insurance policies to include the additional coverage or better still, would legally force the employer to assume these new responsibilities independent of the insurance carrier. This should

eventually bring him to a realization of the value of the measures involved.

At first thought this might appear to throw an additional burden on the employer. Even if it were a burden it would be justified by the existing need but actually any increased initial cost would be amply repaid by increased industrial efficiency yielding dividends which, though somewhat intangible, would be none the less real.

And the physician when treating a patient afflicted with an occupational disease or injury should not focus his attention exclusively on the affected part but give thought to that individual as a whole further he should be cognizant of the fact that that individual is an integral part of an industrial organization, and still further, he should bear in mind that the same individual is a definite part of a social order.

METHODS OF EVALUATING EXTENT OF INJURIES

EARL D. MCBRIDE, M.D., F.A.C.S. OKLAHOMA CITY OKLAHOMA

PHYSICAL disability means a limitation of normal use of the body or parts of the body.

In industry physical injury brings about anatomical and physiological changes which alter the earning capacity and for which society attempts to compensate the individual. The physician, because of his knowledge of the human organism, is called on to analyze and measure the

newly acquired limitations. Difficulties arise, however, when he attempts to evaluate the clinical evidence of physical disability in terms of loss of working capacity. There seems to be no suitable measuring rod as yet devised no definite basis of reasoning no common ground upon which conclusions and opinions may rest. From the medical standpoint there is no reason why the extent of disability and its evaluation should not be diagnosed through just as logical and systematic manner of reasoning as is employed in diagnosing disease.

Most compensation laws base the extent of disability award on anatomical loss rather than on functional incapacity. Amputations at certain points, for instance, have specific awards. If only partial loss has occurred, however, the award can be determined only by apportioning whatever extent the percentage of partial loss approaches the total loss anatomically. That is, if the part is not entirely lost, of what value is it, compared to total loss? At this point the question ceases to be simply one of anatomical deficiency. The lost value of the part no longer can be estimated by its altered shape, size, or motion. It must be measured by establishing the amount of use the part will be to the individual since the changes in shape, size, losses of motion, or other alterations have taken place. It is within the scope of medical science therefore to determine the loss of function, thereby formulating an opinion, expressing the extent of loss.

The extent of evaluation is usually asked for in terms of percentage. A convenient measuring rod, therefore, would have a scale of one hundred units of working capacity. The various factors which constitute normal function for working capacity can be given an estimate of importance by establishing their percentage value on the scale of one

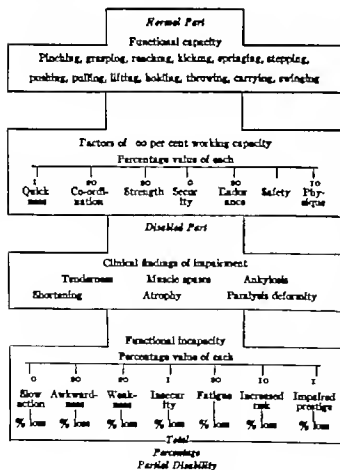

Fig. 1. Basis of evaluation

Now, if we scrutinize the foregoing duties of the plant physician how many of them do we find performed in the average instance? Unfortunately in most cases we find the physician's contact with a factory practically limited to the care of accidents and diseases for which the employer is legally responsible. Are the physicians so negligent in their realization of the potential possibilities of an adequate industrial service or are there other fundamental factors at fault? Much has been said about the ineffectiveness of physicians in dealing with industrial problems—and there is no denying there is some justification for this criticism—but far too little has been said concerning the backwardness of corporations in recognizing the necessity for a complete medical service. It can be stated with confidence that practically every physician in independent practice would be only too glad to comply in so far as he is able with any request made by any company for some service in addition to the routine care of the injured. But such requests are so seldom forthcoming as definitely to dampen any enthusiasm with which the physician might be inclined to enlarge the scope of his affiliation with the factory. This apathy of the smaller corporations is exceedingly deterrent in frustrating the right of their employees to receive the same degree of general medical supervision obtained by those employed by larger corporations having full time physicians.

Our profession should aid in sponsoring an intensive educational campaign to apprise the heads of corporations with the dividends which an adequate medical service pays. Likewise, the matter should be brought before the labor organizations and before the public. If industry makes the demand surely the medical profession will meet it, just as it almost invariably has met other demands in the past. Physicians doing a small amount of corporation practice, who might not be ideally prepared to meet these new phases of industrial service either would have to equip themselves mentally to meet the new conditions or else risk losing whatever corporation contacts they might have acquired. Education of the profession while essential, will be futile in solving the problem unless corporation consciousness is concurrently awakened.

The apathy displayed by most corporations toward their medical service is almost incomprehensible. The average factory superintendent engrossed in his study of production costs, pays little heed to the care of his sick and injured seemingly oblivious to the vital, though somewhat intangible, rôle the welfare of his workers plays in his balance sheets. Before relegating the care of

his employees to a certain physician the head of a factory should investigate that physician's qualifications with the same degree of care exercised in the selection of a physician for his own family.

Another factor in causing this disinterest of the employer arises directly out of the placing of compensation insurance. After receiving insurance coverage the employer only too frequently selects any conveniently located doctor or accepts without question the physician designated by the insurance carrier. Having paid his insurance premium he is disinclined to expend further funds, feeling that he has met the requirements of the compensation law and that the burden now rests with the insurance company. The insurance officer quite naturally is concerned only with fulfilling the requirements of the policy in force and thus all the employee receives is minimal service. It is obviously impractical for most corporations to be self insurers but if they were they would be far more analytical and critical in their selection of medical service than they are now.

A similar situation exists in connection with pre-employment examinations, the great value of which is appreciated by all physicians doing industrial practice, but is absolutely unappreciated by the vast majority of the smaller corporations. Such examinations are not inimical to the workmen, any criticism from their standpoint being more than offset by the early detection of unrecognized physical defects and ailments. Any overtures in this connection made by the plant physician are likely to be viewed askance by the company officials, both on account of the cost and because they are likely to feel the physician is merely trying to increase his own revenue. Were such examinations made legally compulsory both the employer and employee—and that means industry as a whole—would benefit.

Though perhaps apparently irrelevant to this subject the custom of carrying compensation insurance actually has a very decided effect on the relationship between the factory and the physician in independent practice. As such insurance coverage is and doubtless will continue to be an almost universal procedure a study of remedial measures would be timely. For example, if the workmen's compensation laws contained provisions covering the needed additions to the present limited medical service, the situation would be clarified greatly. This would necessitate either corresponding changes in insurance policies to include the additional coverage or better still would legally force the employer to assume these new responsibilities independent of the insurance carrier. This should

eventually bring him to a realization of the value of the measures involved.

At first thought this might appear to throw an additional burden on the employer. Even if it were a burden it would be justified by the existing need but actually any increased initial cost would be amply repaid by increased industrial efficiency yielding dividends which though somewhat intangible would be none the less real.

And the physician when treating a patient afflicted with an occupational disease or injury should not focus his attention exclusively on the affected part but give thought to that individual as a whole. Further, he should be cognizant of the fact that that individual is an integral part of an industrial organization and still further, he should bear in mind that the same individual is a definite part of a social order.

METHODS OF EVALUATING EXTENT OF INJURIES

EARL D. MCBRIDE, M.D. F.A.C.S., OKLAHOMA CITY, OKLAHOMA

PHYSICAL disability means a limitation of normal use of the body or parts of the body. In industry physical injury brings about anatomical and physiological changes which alter the earning capacity and for which society attempts to compensate the individual. The physician, because of his knowledge of the human organism is called on to analyze and measure the

newly acquired limitations. Difficulties arise, however, when he attempts to evaluate the clinical evidence of physical disability in terms of loss of working capacity. There seems to be no suitable measuring rod as yet devised, no definite basis of reasoning, no common ground upon which conclusions and opinions may rest. From the medical standpoint there is no reason why the extent of disability and its evaluation should not be diagnosed through just as logical and systematic manner of reasoning as is employed in diagnosing disease.

Most compensation laws base the extent of disability award on anatomical loss rather than on functional incapacity. Amputations at certain points for instance have specific awards. If only partial loss has occurred, however, the award can be determined only by apportioning whatever extent the percentage of partial loss approaches the total loss anatomically. That is, if the part is not entirely lost, of what value is it, compared to total loss? At this point the question ceases to be simply one of anatomical deficiency. The lost value of the part no longer can be estimated by its altered shape, size or motion. It must be measured by establishing the amount of use the part will be to the individual since the changes in shape, size, losses of motion or other alterations have taken place. It is within the scope of medical science therefore to determine the loss of function, thereby formulating an opinion, expressing the extent of loss.

The extent of evaluation is usually asked for in terms of percentage. A convenient measuring rod, therefore, would have a scale of one hundred units of working capacity. The various factors which constitute normal function for working capacity can be given an estimate of importance by establishing their percentage value on the scale of one

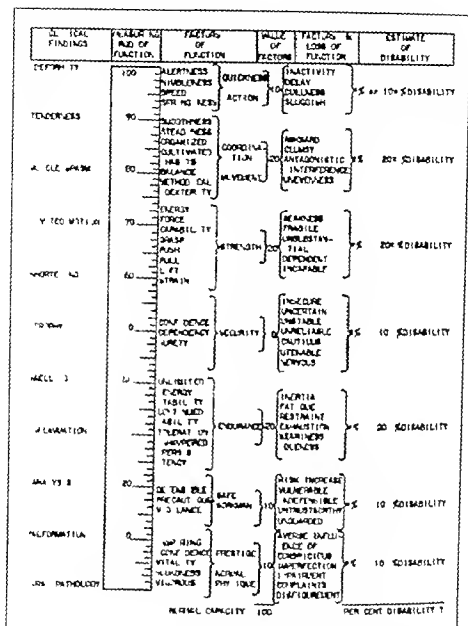

Fig. 2. Evaluation of extent of disability

hundred per cent measuring rod. Their total then would be one hundred per cent. An analysis of the functions of the body from the working capacity standpoint, would seem to be amply expressed in five principal factors, which make possible such acts as grasping throwing jerking pulling pushing turning bending lifting walking jumping and running. These factors are

1. *Quickness of action*, indicating alertness, nimbleness, and speed.

2. *Co-ordination of movements*, indicating smoothness of action, steadiness, dexterity or a synchronizing of movements resulting in proficiency, deftness and good control.

3. *Strength*, indicating physical energy force of intensity power of action as well as muscular ability.

4. *Security*, indicating confidence, habitual trustworthiness and reliability without conscious effort.

Fig. 3. Evaluating a back disability

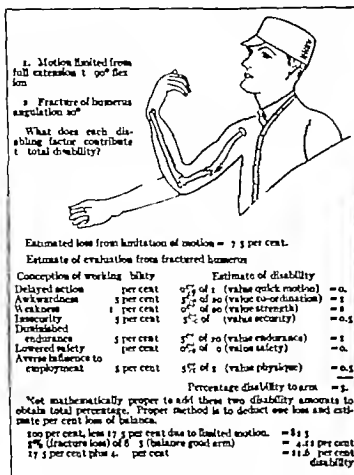

Fig 6 Multiple disability to arm.

5 *Endurance*, indicating toleration vigor, and continuation of activity without interruption.

In respect to industrial injuries, two other factors may be placed on the scale

1 *Safety*, indicating ability to protect oneself and others

2 *Prestige* of normal physique and apparent competency in seeking or retaining employment.

These functional factors may be applied to specific parts of the body. In the hand they would be stated as follows (1) quickness and nimbleness of digital action (2) co-ordination of fingers and thumb in apposing finger tips to thumb and thumb to fingers and palm (3) strength of grip and fast making ability striking slapping holding and pushing power (4) security or reliability of delicate finger sense and dependability on life long habitual and technical finger accomplishments, (5) endurance of punching holding or gripping action.

In respect to the leg, foot and toes, the factors may be considered as follows (1) quickness nimbleness springiness of step and gait (2) co-ordination of feet and toes in smoothness and steadiness of step and gait (3) strength of weight
